5. Stamping assemblies require features, such as flanges, to facilitate joining. These features usually increase the amount of purchase stock and the weight of the end product.
6. Stamping processes work-harden metal to some degree, increasing strength and hardness and decreasing ductility in some areas of the product. These increases are driven by the process, and usually cannot be optimized to the application as can be done in forging. In some cases, work hardening requires intermediate annealing.

Forgings vs. Weldments

Weldments are generally made from bar, tubing, and plate. Part shapes are made by burning, laser cutting, shearing, or sawing, depending on complexity and thickness. Tooling cost is very low but cutting and welding can be labor-intensive.

Weldments may offer an advantage over forgings in low production quantities, but this economic advantage decreases as quantities increase. Applications where production requirements start low can often be introduced as weldments and converted to forgings as production grows.

Forgings can also become part of a weldment. For example, when special features are added to a forging it is sometimes more economical to weld two forgings together than to forge the entire part. A good example is friction welding a bar of steel to a flange to form a long axial shaft.

Forging vs. Foundry Casting

Forgings offer significant advantages over castings in applications where reliability, high tensile strength, or fatigue strength are required. Forgings are free from porosity, which is difficult to eliminate in castings. This is particularly true in areas where geometric transitions occur, which are typically areas of stress concentration.

The superior fracture toughness of forgings often must be considered when designing equivalent castings by applying a "casting factor." This casting factor imposes a weight penalty that is often enough to make forgings the more economical choice.

Forging vs. Investment Casting

Investment casting, sometimes known as the "lost-wax" process, is used with a wide range of alloys, including carbon and alloy steels, stainless steels, titanium, nickel, cobalt, and aluminum alloys. Tools consist of aluminum molds for injection molding the wax patterns. They are relatively inexpensive and require very little maintenance.

The investment casting process is more labor-intensive than forging, and is more suited to lower production quantities. Investment casting is most advantageous for small- and medium-size castings of highly complex shapes that require extremely tight dimensional precision and good surface quality.

Forging vs. CNC Machining

There is virtually no limit to the shapes that can be produced by CNC machines. In most cases, standard cutting tools are used, eliminating the need to purchase special tooling. Processing and material costs are generally high because much of the purchased stock is removed. Hogouts are useful for complex or precision components in very low quantities. They can also be used on a limited basis for prototype forgings. Forgings generally exhibit superior directional properties and fatigue performance due to grain flow.

Forging vs. Powder Metallurgy

Conventional powder metallurgy (P/M), metal injection molding (MIM), and powder forging (P/F) are the three most commonly specified powder metallurgy processes. MIM is currently limited to very small components, up to approximately 100 g of complex configuration. It is rarely an alternative to forging. Conventional P/M and P/F may be alternatives in some applications.

Conventional P/M produces very close dimensional precision, but the process is characterized by porosity, which reduces mechanical properties. Tensile and yield strengths decline approximately in proportion to the level of porosity. Ductility and dynamic properties, such as impact toughness, fracture toughness, and fatigue strength, are usually much lower than for forgings. Additional processes, such

F

as infiltration and special sintering procedures, can improve these properties. However, the metallurgical properties of such products are not equivalent to forgings made from similar alloys.

Material properties of P/M parts approach those of forgings only when the porosity is reduced to 0.5% or less. Generally, this can only be achieved by P/F. P/F is an alternative to impression die forging for small- and medium-sized components with a high degree of symmetry and high production volumes, such as automotive connecting rods.

Forgings vs. Reinforced Plastics and Composites

Reinforced plastics and composites generally utilize thermoset plastics, and occasionally thermoplastics, as a matrix. Reinforcing fibers of glass, mineral, carbon, and aramid are added to increase strength and stiffness. These materials are well established in applications where low weight is essential and increased cost can be tolerated, such as aerospace applications. Regardless of the reinforcing fibers used, the operating temperature range of reinforced plastics and composites is limited by the polymer matrix materials.

Forgings offer advantages of lower cost and higher production rates. Forging materials outperform composites in almost all physical and mechanical properties, especially impact toughness, fracture toughness, and compression strength.

Forking

A phenomenon in which a propagating fracture in a ceramic system branches into two or more new fractures, each separated from its immediate neighbor by an acute angle.

Form Block

Tooling, usually the male part, used for forming sheet-metal contours; generally used in *rubber-pad forming*.

Form Cutter

Any cutter, profile sharpened or cam relieved, shaped to produce a specified form on the work.

Form Die

A die used to change the shape of a sheet metal blank with minimal plastic flow.

Form Grinding

Grinding with a wheel having a contour on its cutting face that is a mating fit to the desired form.

Form Machining/Tool Machining

Processes which utilize a cutting tool shaped to the final intended profile.

Form Rolling

Hot rolling to produce bars having contoured cross-sections; not to be confused with *roll forming* of sheet metal or with *roll forging*.

Form Tool

A single-edge, nonrotating cutting tool, circular or flat, that produces its inverse or reverse form counterpart upon a workpiece.

Formability

The ease with which a metal can be shaped through plastic deformation. Evaluation of the formability of a metal involves measurement of strength, ductility, and the amount of deformation required to cause fracture. The term *workability* is used interchangeably with *formability*; however, *formability* refers to the shaping of sheet metal, while *workability* refers to shaping materials by *bulk forming*. See also *forgeability*.

Formaldehyde

Also called *methylene oxide*. A colorless, poisonous gas of composition HCHO . It is very soluble in water and is marketed as a 40% solution by volume, 37 by weight, under the name of *formalin*. The commercial formalin is a clear, colorless liquid with a specific gravity of 1.075–1.081. The material is obtained by oxidation from methyl alcohol. It is used in making plastics, as a reducing agent, as a disinfectant, and in the production of other chemicals, such as ethylene glycol, hexamethylenetetramine, pentaerythritol, and butadiene. *Trioxane* is polymerized formaldehyde, or a ring compound of anhydrous formaldehyde. It is marketed as colorless crystals of a pleasant ether-alcohol odor. It is used as a source of dry formaldehyde gas, as a tanning agent, and as a solvent. It burns with a hot, odorless flame, and is used in tablet form to replace solidified alcohol for heating.

Form-and-Spray

Technique for thermoforming plastic sheet into an end product and then backing up the sheet with *spray-up* reinforced plastics.

Forming (Ceramics and Glasses)

(1) The shaping or molding of ceramic ware. (2) The shaping of hot glass.

Forming (Metals)

(1) Making a change, with the exception of shearing or blanking, in the shape or contour of a metal part without intentionally altering its thickness. (2) The plastic deformation of a billet or a blank sheet between tools (dies) to obtain the final configuration. Metal-forming processes are typically classified as *bulk forming* and *sheet forming*. Also referred to as *metalworking*.

Forming (Plastics)

A process in which the shape of plastic pieces such as sheets, rods, or tubes is changed to a desired configuration. See also *thermoforming*. The use of the term *forming* in plastics technology does not include such operations as molding, casting, or extrusion, in which shapes or pieces are made from molding materials or liquids.

Forming Limit Diagram (FLD)

A diagram in which the major strains at the onset of necking in sheet-metal are plotted vertically and the corresponding minor strains are plotted horizontally. The onset-of-failure line divides all possible strain combinations into two zones; the safe zone (in which failure during forming is not expected) and the failure zone (in which failure during forming is expected).

Forming Processes

Those processes that change the shape of material along its major axis without substantially changing its cross-section, for example, bending, coiling, or twisting.

Form-Relieved Cutter

A cutter so relieved that by grinding only the tooth face the original form is maintained throughout its life.

Formvar

A plastic material used for the preparation of replicas or for specimen-supporting membranes.

Formvar Replica

A reproduction of a surface in a plastic Formvar film. See also *replica*.

Forsterite

A magnesium silicate mineral of composition $2\text{MgO}\cdot\text{SiO}_2$, which is usually produced synthetically as a ceramic raw material, but it may also be a reaction-produced phase and fired ceramics used in refractory brick.

Forward Extrusion

Same as direct extrusion. See *extrusion*.

Forward Welding

See *forehand welding*.

Fouling

(1) Unwanted deposits particularly barnacles and weeds on the submerged surface of ships or other marine equipment. (2) Unwanted mineral or other deposits on, for example, the interior of pipework or boiler gas passages. (3) An accumulation of deposits. This term includes accumulation and growth of marine organisms on a submerged metal surface and also includes the accumulation of deposits (usually inorganic) on heat exchanger tubing. See also *biological corrosion*.

Fouling Organisms

Any aquatic organism with a sessile adult stage that attaches to and fouls underwater structures of ships.

Foundry

A commercial establishment or building where metal castings are produced.

Foundry Returns

Metal in the form of gates, sprues, runners, risers, and scrapped castings of known composition returned to the furnace for remelting.

Four Point Bending

A test, or other loading situation, in which the component, usually a bar, is supported at two points toward its extremities and the load is applied through two points symmetrically located between the supports. A feature of such loading is that the stress is uniform over the length between the two inner points, unlike three-point bending.

Four-Harness Satin

A fabric weave, also called *crowfoot satin* because the weaving pattern, when laid out on cloth design paper, resembles the imprint of crow's foot. In this type of weave there is a three-by-one interlacing. That is, a filling thread floats over the three warp threads and then under one. The two sides of the fabric have different appearances. Fabrics with this weave are more pliable than either the plain or basket weaves and, consequently, are easier to form around curves. See the term *crowfoot satin*.

Four-High Mill

A type of rolling mill, commonly used for flat-rolled mill products, in which two large-diameter backup rolls are employed to reinforce two smaller work rolls, which are in contact with the product. Either the work rolls or the backup rolls may be driven. Compare with *two-high mill* and *cluster mill*.

Fourier Transform

(1) A mathematical process for changing the description of a function by giving its value in terms of its sinusoidal spatial (or temporal) frequency components instead of its spatial coordinates (or vice versa). (2) An analytical method used automatically in advanced forms of spectroscopic analysis such as infrared and nuclear magnetic resonance spectroscopy.

Fourier Transform Infrared (FT-IR) Spectrometry

A form of infrared spectrometry in which data are obtained as an interferogram, which is then Fourier transformed to obtain an amplitude vs. wavenumber (or wavelength) spectrum.

Four-Point Press

A press whose slide is actuated by four connections and four cranks, eccentrics, or cylinders, the chief merit being to equalize the pressure at the corners of the slides.

FP Fiber

A polycrystalline all-alumina fiber (>99% Al_2O_3). A ceramic fiber useful for high temperature (1370°C–1650°C, or 2500°F) composites.

Fraction

In powder metallurgy, the portion of a powder sample that lies between two stated particle sizes.

Fractography

(1) Descriptive treatment of fracture of materials, with specific reference to photographs of the fracture surface. Macrofractography

F

involves photographs at low magnification ($<25\times$); microfractography, photographs at high magnification ($>25\times$). (2) The examination of fracture surfaces under a conventional light microscope or in a scanning electron microscope. Normally no preparation of the surface, apart from cleaning, is involved although replication is common.

Fracture

A crack or break or the process of cracking, see *break*. Often “fracture” without qualification has implications of low ductility whereas “rupture” may imply significant ductility but there are no fully reliable rules and “ductile fracture” is quite acceptable.

Fracture (Composites)

The separation of a body. Defined both as rupture of the surface without complete separation of the laminate and as complete separation of a body because of external or internal forces. Fractures in continuous fiber reinforced composites can be divided into three basic fracture types: intralaminar, interlaminar, and translaminar. Translaminar fractures are those oriented transverse to the laminated plane in which conditions of fiber fracture are generated. Interlaminar fracture, on the other hand, describes failures oriented between plies, whereas intralaminar fractures are those located internally within a *ply*.

Fracture (Metals)

The irregular surface produced when a piece of metal is broken. See also *brittle fracture*, *cleavage fracture*, *crystalline fracture*, *decohesive rupture*, *dimple rupture*, *ductile fracture*, *fibrous fracture*, *granular fracture*, *intergranular fracture*, *silky fracture*, and *transgranular fracture*.

Fracture Analysis

Any technique, with particularly numerical ones, based on the data derived from examining and measuring features on a fracture surface. For example, detailed measurements of the number and spacing of beach marks on a fatigue fracture can indicate key factors such as the date of initiation, the number of cycles and the levels of stress.

Fracture Appearance Transition Temperature (FATT)

The temperature at which a fracture faces 50% cleavage and 50% ductile. See *impact test*.

Fracture Ductility

The true plastic strain of fracture.

Fracture Energy

The energy input required to produce unit area increase of crack face. Since any crack has two faces the fracture energy is half the fracture toughness.

Fracture Grain Size

Grain size determined by comparing a fracture of a specimen with a set of standard fractures. For steel, a fully martensitic specimen is generally used, and the depth of hardening and the prior austenitic grain size are determined.

Fracture Mechanics—Also Termed Linear Elastic Fracture Mechanics (LEFM)

The study of the mechanics of crack growth, in particular stress-related matters in the zone of material at the crack tip. Note that although this definition excludes crack initiation in a defect-free material, many apparently sound components contain crack-like features. Examples include, on a macro scale, the surface irregularities on welds (see *weld defects*) or, on a microscopical scale, the inclusions inevitable in many metals. The principles of fracture mechanics are most readily applicable to low ductility mechanical damage mechanisms such as brittle fracture and fatigue but they are also applied, perhaps with more difficulty to other mechanisms such as stress corrosion and creep. Clearly, the severity of loading in the presence of a crack is influenced by both the size of the externally imposed load and the size of the crack, and hence, a basic requirement is to develop a parameter reflecting these two variables that is measurable and calculable in a manner analogous to stress in an uncracked component. This parameter is termed stress intensity factor, “ K ” and can be defined as the measure of the elastic stress field in the vicinity of a crack tip. Stress intensity should not, therefore, be confused with stress concentration factor or even stress intensification factor since the latter two terms are not readily measurable and, at best, are quantified only as a multiplication factor. Cracks can extend in three modes depending on the form of loading: mode I—the crack opening mode (simple tensile loading), mode II—the edge sliding mode (in-plane shear loading), and mode III—the shear mode (out-of-plane shear loading). Of these, the opening mode is by far the most common but, where necessary, the relevant mode is indicated by the appropriate subscript, for example, K_I , K_{II} , or K_{III} . Basic fracture mechanics deals with idealized circumstances where all stresses in the crack tip zone are elastic and K increases to a critical stress intensity, termed K_C (or, if appropriate, K_{IC} , etc.), at which the crack will extend without any plastic deformation. Such behavior is, by definition brittle and for brittle materials K_C is a measure of fracture toughness. In practice, some plastic deformation is inevitable but, where it is slight, the basic concepts can be applied with adequate accuracy. However, where the amount of plasticity is large, relative to the crack size, then more complex treatments are required. These are usually based on the J integral which can be considered analogous to K with corrections for plasticity. Effectively elastic conditions are encountered in components which are thick relative to the crack size. In these circumstances, the potential local plasticity at the highly stressed crack tip is constrained to a very small volume by the surrounding bulk of lower stress material. This causes stresses in the transverse directions and is described as a condition of plane strain, hence the use of the term plane strain fracture toughness when referring to K_{IC} . The term plane stress refers to circumstances where the tensile stress is uniaxial, that is, there is no stress in the transverse directions and all material in the section carries the net section stress, that is, the total applied load divided by the full cross section. Such circumstances are encountered in crack-free material or at a crack that is large relative to the plate thickness. In the latter case of bulk yielding ahead of the crack allows stress redistribution to eliminate stresses in the transverse directions. Generalizing, if the net section stress does not exceed about 0.8 of the yield strength, the plastics will be sufficiently small for plane strain to apply and hence for calculations based on K to be reasonably accurate. See also *fracture toughness*; *linear elastic fracture mechanics*.

Fracture Strength

The normal stress at the beginning of fracture. Calculated from the load at the beginning of fracture during a tension test and the original cross-sectional area of the specimen.

Fracture Stress

The true, normal stress on the minimum cross-sectional area at the beginning of fracture. The term usually applies to tension tests of unnotched specimens.

Fracture Surface Markings

Fracture surface features that may be used to determine the fracture origin location and the nature of the stress that produced the fracture.

Fracture System

That family of related fracture surfaces lying within an object, having a common cause and origin.

Fracture Test

Test in which a specimen is broken and its fracture surface is examined with the unaided eye or with a low-power microscope to determine such factors as composition, grain size, case depth, or discontinuities.

Fracture Toughness

A generic term for measures of resistance to extension of a crack. The term is sometimes restricted to results of *fracture mechanics* tests, which are directly applicable in fracture control. However, the term commonly includes results from simple tests of notched or pre-cracked specimens not based on fracture mechanics analysis. Results from tests of the latter type are often useful for fracture control, based on either service experience or empirical correlations with fracture mechanics tests. See also *stress-intensity factor*.

Fracture Transition

Same as *fracture appearance transition*.

Fragmentation

The subdivision of a grain into small, discrete crystallite outlined by a heavily deformed network of intersecting slip bands as a result of cold working. These small crystals or fragments differ in orientation and tend to rotate to a stable orientation determined by the slip systems.

Fragmented Powder

A powder obtained by fragmentation and mechanical comminution into fine particles.

Frame

The main structure of a forming or forging press.

Francium

A metallic element, one of the alkali group.

Frank-Condon Principle

The principle that states that the transition from one energy state to another is so rapid that the nuclei of the atoms involved can be considered stationary during the transition.

Frank-Rhead Source

A mechanism capable of generating dislocations. The mechanism can be visualized as an edge dislocation anchored at its two ends and subjected to a stress that causes it to bow outwards forming loops around the anchor points. As the loops grow, the structure becomes unstable and jumps to form a new continuous loop dislocation round the original source, which remains to trigger further loops.

Freckling

A type of segregation revealed as dark spots on a macroetched specimen of a consumable-electrode vacuum-arc-remelted alloy.

Free Bend

The bend obtained by applying forces to the ends of the specimen without the application of force at the point of maximum bending.

Free Carbon

The part of the total carbon in steel or cast iron that is present in elemental form as graphite or *temper carbon*. Contrast with *combined carbon*.

Free Corrosion Potential

Corrosion potential in the absence of net electrical current flowing to or from the metal surface.

Free Cutting/Machining

A metal that has been treated usually by the deliberate introduction of impurities, to improve its machining characteristics, in particular to ensure that material being cut away is released as small chips rather than continuous strands. The impurities form an even dispersion of particles of a size large enough to serve as chip breakers but not so large that they have an acceptable effect on mechanical properties. The effect is achieved, for example, in steels by appropriate quantities of manganese sulfide inclusions and in brass by additions of lead. Machining characteristics can also, in some cases, be improved by heat treatments that influence the distribution and size of precipitates or that induce some beneficial grain structure. For example, some steels can develop a blocky structure with a favorable ferrite/pearlite distribution. The effect of such treatments may not be so pronounced as that induced by inclusions but it is useful where any inclusions are unacceptable, as in the case of steels for ball and roller bearings.

Free Electron Theory

This suggests that the valence electrons in a metallic bond form an electron cloud or electron gas in which there is no constraint on their movement. Subsequently, the energy band theory was developed to better explain phenomena such as semiconduction.

F

Free Ferrite

(1) Ferrite that is formed directly from the decomposition of hypoeutectoid austenite during cooling, without the simultaneous formation of cementite. (2) Ferrite formed into separate grains and not intimately associated with carbides as is pearlite. Also called *proeutectoid ferrite*.

Free Fit

Any of various clearance fits for assembly by hand and free rotation of parts. See also *running fit*.

Free Machining

Pertains to the machining characteristics of an alloy to which one or more ingredients have been introduced to produce small broken chips, lower power consumption, better surface finish, and longer tool life; among such additions are sulfur or lead to steel, lead to brass, lead and bismuth to aluminum, and sulfur or selenium to stainless steel.

Free Radical

Any molecule or atom that possesses one unpaired electron. In chemical notation, a free radical is symbolized by a single dot (to denote the odd electron) to the right of the chemical symbol.

Free Rolling

Rolling in which no traction is deliberately applied between a rolling element and another surface.

Free Rotation

The rotation of atoms, particularly carbon atoms, about a single bond. Because the energy requirement is only a few kcal, the rotation is said to be free if sufficient thermal energy is available.

Free Vibration

A technique for performing dynamic mechanical measurements in which the sample is deformed, released, and allowed to oscillate freely at the natural resonant frequency of the system. Elastic modulus is calculated from the measured resonant frequency, and damping is calculated from the rate at which the amplitude of the oscillation decays.

Free Wall

The portion of a *honeycomb* cell wall that is not connected to another cell.

Free-Energy Diagram

A graph of the variation with concentration of the Gibbs free energy at constant pressure and temperature.

Free-Energy Surface

In a ternary or higher order free-energy diagram, the locus of points representing the Gibbs free energy as a function of concentration, with pressure and temperature constant.

Free-Radical Polymerization

A type of polymerization in which the propagating species is a long-chain free radical initiated by the introduction of free radicals from thermal or photochemical decomposition of an initiator molecule.

Freezing Point

See preferred term *liquidus* and *solidus*. See also *melting point*.

Freezing Range

That temperature range between *liquidus* and *solidus* temperatures in which molten and solid constituents coexist.

Frequency

The number of cycles per unit time. The recommended unit is the hertz, Hz, which is equal to 1 cycle/s.

Frequency Distribution

The way in which the frequencies of occurrence of members of a population, or a sample, are distributed according to the values of the variable under consideration.

Fresnel Fringes

A class of diffraction fringes formed when the source of illumination and the viewing screen are at a finite distance from a diffracting edge. In the electron microscope, these fringes are best seen when the object is slightly out of focus.

Fretting

A type of wear that occurs between tight-fitting surfaces subjected to cyclic relative motion of extremely small amplitude. Usually, fretting is accompanied by corrosion, especially of the very fine wear debris. Also referred to as *fretting corrosion* and *false Brinelling* (in rolling-element bearings).

Fretting Corrosion

(1) The accelerated deterioration at the interface between contacting surfaces as the result of corrosion and slight oscillatory movement between the two surfaces. (2) A form of *fretting* in which chemical reaction predominates. Fretting corrosion is often characterized by the removal of particles and subsequent formation of oxides, which are often abrasive and so increase the wear. Fretting corrosion can involve other chemical reaction products, which may not be abrasive.

Fretting Fatigue

Fatigue fracture that initiates at a surface area where fretting has occurred. The progressive damage to a solid surface that arises

from fretting. *Note:* If particles of wear debris are produced, then the term *fretting wear* may be applied.

Fretting Wear

Wear arising as a result of *fretting*.

Friction

The resulting force tangential to the common boundary between two bodies when, under the action of an external force, one body moves or tends to move relative to the surface of the other. The term friction is also used, incorrectly, to denote *coefficient of friction*. It is vague and imprecise unless accompanied by the appropriate modifiers, such as *dry friction* or *kinetic friction*. See also *static coefficient of friction*. The force acting between two contacting bodies in motion relative to each other. The Laws of Friction are (1) The static frictional force is proportional to the load acting normal to the interface. (2) The frictional force is independent of the interfacial area. (3) Sliding friction is less than the limiting static friction.

Friction Coating/Surfacing

The deposition of a coating by a rod of material which rotates as it bears heavily against the component to be coated. The rotation initially causes friction heating to a temperature near the melting point of the rod material and secondly scours the receiving surface allowing a good bond with the deposited metal. A wide range of materials including hard facing alloys can be deposited.

Friction Coefficient

See *coefficient of friction*.

Friction Cutting/Sawing

Operations in which frictional heating plays a significant role in melting or softening the material being cut. In the case of friction sawing the blade is usually toothed to assist metal removal but in friction cutting the blade may be plain edged.

Friction Force

The resisting force tangential to the interface between two bodies when, under the action of an external force, one body moves or tends to move relative to the other.

Friction Grip Bolting

A bolted joint which relies on having sufficient preload in the bolts to develop a high level of friction between the mating faces of the joint. Loads across the joint are then carried by friction in the parent materials rather than by the bolts and shear.

Friction Material

A sintered material exhibiting a high coefficient of friction design for use where rubbing or frictional wear is encountered—for example, aircraft brake linings and clutch facings on tractors, heavy trucks, and earth-moving equipment. Friction materials consist of a dispersion of friction-producing ingredients in a metallic matrix.

Friction Polymer

An amorphous organic deposit that is produced when certain metals are rubbed together in the presence of organic liquids or gases. Friction polymer often forms on moving electrical contacts exposed to industrial environments. The varnish-like film will attenuate or modify transmitted signals.

Friction Soldering

See preferred term *abrasion soldering*.

Friction Welding

Welding in which heat is produced by the friction between two contacting components moving relatively to each other. The term usually refers to a production process in which two components are forced together while one is rapidly rotated or otherwise moves relative to the other. The relative movement causes heating, disrupts surface films allowing contact between clean surfaces and produces local deformation. When these effects reach an optimum stage, the movement is sharply halted and the interfacial force is considerably increased leading, and suitable cases, to strong joints even between materials not readily welded by other techniques. The friction welding effect may occur unintentionally as a result of adhesive wear in which case it is usually termed *seizure*.

Friction Welding (Metals)

A solid-state process in which welds are made by holding a nonrotating workpiece in contact with a rotating workpiece under constant or gradually increasing pressure until the interface reaches the welding temperature and rotation can be stopped.

Friction Welding (Plastics)

A method of welding thermoplastic materials in which the heat necessary to soften the components is provided by friction.

Frictive Track

In glass, a series of crescent cracks lying along a common axis, paralleling the direction of frictive contact. Also known as a chatter sleek.

Fringes

Bands of light of varying intensity or color produced by interference effects.

Frit

A glass produced by *fritting*, which contains fluxing material and is employed as a constituent in a glaze, body, or other ceramic composition.

Fritting

The rapid chilling of the molten glassy material to produce frit. See *sintering*.

F

Frost Line

In the extrusion of polyethylene lay-flat film, a ring-shape zone located at the point where the film reaches its final diameter. This zone is characterized by a frosty appearance on the film caused when the film temperature falls below the softening range of the resin.

Frosted Area

See *hackle*.

Frosting

A form of ball bearing groove damage, and tearing as a frosted area, suggestive that surface distress has occurred.

Frothing

A technique for applying urethane foam in which blowing agents or tiny air bubbles are introduced under pressure into the liquid mixture of foam ingredients.

Frozen Equilibrium

A condition in which a material is unable to progress to the theoretical equilibrium state because there is insufficient thermal energy to allow diffusion.

Frozen Stress

A photo-elastic stress analysis technique.

FRP

See *fiber-reinforced plastic*.

Fuel Briquettes

Also termed *coal briquettes*. Various-shaped briquettes made by compressing powdered coal, usually with an asphalt or starch binder, but sometimes as *smokeless fuel* without a binder. They are sometimes also made waterproof by coating with pitch or coal tar. They have a great advantage over raw coal that they do not take up large amounts of water, as coal does, and thus have uniformity of firing. Fuel briquettes are made from anthracite screenings usually mixed with bituminous screenings, as the bituminous coals require no binders. The usual forms of the briquettes are pillow-shaped, cubic, cylindrical, ovoid, and rectangular. The term *packaged fuel* is used for cube-shaped briquettes wrapped in paper packages, used for hand firing in domestic furnaces. *Charcoal briquettes* for home fuels are charcoal powders pressed with a starch binder. *Fuelettes*, solid fuel made from the low-grade nonrecyclable portion of the mix-paper waste, are intended for cofiring with coal in industrial boilers. They are best suited for solid-fuel and fluidized-bed boilers. Because they are sulfur-free, their use reduces emissions of sulfur dioxide.

Fuel Cells**Solid Oxide Fuel Cells**

Solid oxide fuel cells (SOFC) can be classified in terms of their structures into tubular, planar, and honeycomb types. Among them, a planar SOFC will be the most suitable for large power

plant utilization because the higher power density can be expected. Furthermore, well-established ceramic processing methods such as the tape-casting method can be applied to fabricate planar SOFC components cheaply and easily.

SOFC are high-temperature (900°C–1000°C), ceramic, electrochemical reactors that directly convert chemical into electrical energy. The basic unit of a cell consists of two porous gas-diffusion electrodes separated by a gastight (i.e., dense), oxygen-ion-conducting electrolyte. Yttria-stabilized zirconia (YSZ) has been most popularly used as electrolyte material, because of its relatively high ionic conductivity and high chemical stability both in reducing and oxidizing atmospheres. The perovskite $\text{La}_{1-x}\text{Sr}_x\text{MnO}_{3-y}$ (SLM, with $0 < x < 0.5$) has been used mostly as cathode material and the cermet Ni/8 mol% yttria-stabilized zirconia (8YSZ) has been used as anode material.

Two well-known methods for attaching the LSM to the YSZ electrolyte are plasma spraying and sputtering. Because these are gas-phase processing methods, significantly good contact conditions between the electrode and the electrolyte can be obtained; a thin and homogenous electrode layer can be produced on the electrolyte.

For optimum SOFC performance, the electrodes require good lateral conductivity, electrochemical activity, and chemical stability toward the electrolyte and gas environment. These factors depend on the composition and microstructure of the electrode, which is determined by the nature of the starting powder in the applied manufacturing technique.

Application

The high-temperature SOFC using zirconia electrolyte are being considered for power generation because they are expected to provide high energy efficiency, yet produce a low level of pollutant gases. The SOFC plants will be operated at high temperatures near 1000°C, and different cell materials will be exposed to either oxidizing or reducing atmosphere over a long time. Hence, the degradation of the cell performance due to the reaction between electrode materials and the zirconia electrolyte may become an important factor in determining the service life.

Other Cells

An environmentally cleaner way to generate electricity, known as molten carbonate fuel cell technology, could significantly increase the demand for nickel over the next decade.

Stationary plants that will use H_2 and O_2 to generate electrical power, with water and heat as the sole byproducts, could be built. These quiet, nonpolluting plants could become an important part of the power industry in the twenty-first century.

If the present design concepts hold up, the anodes and cathodes of these massive power plants will be made of porous nickel alloys. Typically, the anode is a Ni–Cr alloy, and the cathode is composed of a lithiated NiO. Nickel catalysts (supported either on MgO or Li–Al–dioxide) are also required to reform hydrocarbon fuel such as natural gas, producing H_2 gas, which is needed in the fuel cell.

Fuel cells may be a preferred technology of the future for perfluorinated polymers, which are critical components in membrane fuel cells. Membranes made with perfluorinated polymers act as a separator and electrolyte to allow the fuel cell to run at high current densities and voltages.

Last are the proton exchange membrane (PEM) fuel cells for major office buildings and for the automotive industry.

The fuel cells in a power plant, for example, if installed in a 52-story office building, will convert natural gas to electrical energy through a series of chemical processes. Combined, two cells will

generate 400 kW of building power, including external lighting and signage for the building façade and hot water for thermal heat.

Similar to the common battery, the fuel cell uses an electrochemical process to convert chemical energy found in H_2 and O_2 into electricity and water. Fuel cells are more efficient than internal-combustion engines and are virtually pollution- and noise-free. Stationary fuel cells can be powered by gasoline, natural gas, or methanol. Cells designed for cars are powered by gasoline.

The transportation market is the next frontier—to advance PEM technology for so-called electric cars. The resulting fuel cell can produce more than 50 kW of power, enough to power a midsize car. The extraordinary progress being made in using technology to reduce greenhouse gases, improve the air that we breathe, and use our energy more efficiently is being advanced in automotive technology.

Fuel Element

A component for a nuclear reactor comprising a fissionable material in a metal sheath that provides protection and support and retains any fission products.

Fuel Gases

Gases usually used with oxygen for heating such as acetylene, natural gas, hydrogen, propane, methyl-acetylene propadiene stabilized, butane, methane, coal gas and other synthetic fuels are hydrocarbons.

Fuel Oil

Distillates of petroleum or shale oil used in diesel engines and in oil-burning furnaces. True fuel oils are the heavier hydrocarbons in kerosene, but the light or distillate oils are used largely for heating and the heavy or residual oils for industrial fuels. In some cases, only the light oils, naphtha and gasoline, are distilled from petroleum, and the residue is used for fuel oil, but this is wasteful of the lighter oils. Commercial grades of *furnace oil* for household use and *diesel oil* for trucks may be low grades of kerosene. *Gas oil*, which receives its name from its use to enrich fuel gas and increase the luminance of the flame, is also used as a fuel oil in engines. *Bunker C oil*, for diesel engines, is a viscous black oil.

Fuels

The term normally covers a wide range, since innumerable organic materials can be used as fuel. Coal, oil, or natural gas or products derived from them are the basic industrial fuels, but other materials are basic in special situations, such as sawdust in lumbering areas and bagasse in sugarcane areas.

But modern technical reference to fuels generally applies to *high-energy fuels* for jet engines, rockets, and special-use propellants; and the comparisons of these fuels are in terms of *specific impulse*, which is the thrust in pounds per pound of propellant per second. The molecular weight of the products produced by the reaction of a fuel must be extremely low to give high specific impulse, that is, above 400. Hydrogen gives a high specific-impulse rating, but it has very low density in the liquid state and other unfavorable properties, so that it is usually employed in compounds. The initial impulse of a rocket is proportional to the square root of the combustion temperature of the fuel. *Hydrogen fuels* reacted with pure oxygen produce temperatures above 5000°F (2760°C), and

some fuels may react as high as 9000°F (4982°C). Aluminum powder or lithium added to hydrogen increases the efficiency. *Boron fuels* in general release 50% more thermal energy than petroleum hydrocarbons. The first Saturn space rocket had kerosene-liquid oxygen in the first stage and liquid hydrogen-oxygen in the following three stages. *Solid rocket fuels*, designed for easier handling, have a binder of polyurethane or other plastic. *Fuel oxidizers*, for supplying oxygen for combustion, may be ammonium, lithium, or potassium perchlorates. In solid fuels, oxidizers make up as much as 80% of the total.

A *monopropellant*, high-energy fuel is a chemical compound which, when ignited under pressure, undergoes an exothermic reaction to yield high-temperature gases. Examples are nitromethane, methyl acetylene, ethylene oxide, and hydrogen peroxide. Gasoline oxidized by hydrogen peroxide gives a specific impulse of 248, while pentaboranes under pressure and oxidized with hydrogen peroxide give a specific impulse of 363. *ASTM fuel A*, for jet engines, is isooctane, and *ASTM fuel B* is isooctane and toluene. *Turbine jet fuel*, or *JP fuel*, has been the naphtha-based *JP-4* for military aircraft and the kerosene-based *JP-8* for commercial aircraft, with JP-4 having a lower flashpoint, or ignition temperature. However, military aircraft are switching to JP-8 in the interest of greater safety on impact. Besides its higher flashpoint, flame spread of a pool of JP-8 is much slower. The *naphthalenes*, such as *decahydronaphthalene*, have high thermal stability, and they have a high density which gives high thermal energy per unit volume. *Bio Oil*, made from sugarcane bagasse, is a clean fuel for gas turbines, diesels, and boilers.

Sodium boron hydride, a white crystalline solid of composition $NaBH_4$, made by reacting sodium hydride with methyl borate, is also used to produce the bore range for fuels. Any element or chemical which causes spontaneous ignition of a rocket fuel is called a *hypergolic material*.

Chemical radicals are potential high-energy fuels, as the recombining of them produces high specific impulses. But chemical radicals normally exit only momentarily and are thus not stable materials and, in general, are not commercial fuels. *Ion propellants* operate on the principle that like charges repel each other, and the fuel is in ion-plasma jet actually formed outside the engine. The original fuel is a metal such as cesium from which electrons can be stripped by passing the vapor through a hot screen, leaving positive cesium ions, which are formed into a beam and exhausted from the jet thrust to be electronically neutralized in the ionized plasma.

Fugitive Binder

An organic substance added to a metal powder to enhance the bond between the particles during compaction and thereby increase the green strength of the compact, and which decomposes during the early stages of the sintering cycle.

Full Annealing

(1) An imprecise term that denotes an annealing cycle to produce minimum strength and hardness. For the term to be meaningful, the composition and starting condition of the material at the time-temperature cycle used must be stated. (2) Annealing steel by heating into the austenitic region and cooling slowly, usually in the furnace, as opposed to normalizing or subcritical annealing. See *steel*.

Full Center

Mild waviness down the center of a metal sheet or strip.

F

Full Fillet Weld

A fillet weld whose size is equal to the thickness of the thinner member joined.

Full Hard

A *temper* of nonferrous alloys and some ferrous alloys corresponding approximately to a cold-worked state beyond which the material can no longer be formed by bending. In specifications, a full hard temper is commonly defined in terms of minimum hardness or minimum tensile strength (or, alternatively, a range of hardness or strength) corresponding to a specific percentage of cold reduction following a full anneal. For aluminum, a full hard temper is equivalent to a reduction of 75% from *dead soft*; for austenitic stainless steels, a reduction of about 50%–55%.

Full Journal Bearing

A journal bearing that surrounds the journal by a full 360°.

Full Mold

A trade name for an expendable pattern casting process in which the polystyrene pattern is vaporized by the molten metal as the mold is poured. The metal rises to fill the mold which can be of highly complex form. See the term *lost foam casting*.

Full Width at Half Maximum (FWHM)

A measure of resolution of a spectrum or chromatogram determined by measuring the peak width of a spectral or chromatographic peak at half its maximum height.

Full-Automatic Plating

Electroplating in which the work is automatically conveyed through the complete cycle.

Full-Contour Length

The length of a fully extended polymer chain.

Fuller (Fullering Impression)

Portion of the die used in hammer forging primarily to reduce the cross section and to lengthen a portion of the forging stock. The fullering impression is often used in conjunction with an *edger* (*edging impression*).

Fullerenes

Fullerenes are a family of molecules that contain an even number of carbon atoms in a closed cage. The molecule is a hollow, pure carbon molecule in which the atoms lie at the vertices of a polyhedron with 12 pentagonal faces and any number (other than one) of hexagonal faces. The fullerenes were discovered as a consequence of astrophysically motivated chemical physics experiments that were interpreted by using geodesic architectural concepts. Fullerene chemistry, a field that appears to hold much promise for materials development and other applied areas, was born from pure fundamental science.

Buckminster fullerene (C_{60} or fullerene-60) is the archetypal member of the fullerenes. Other stable members of the fullerene family have similar structures. The fullerenes can be considered, after graphite and diamond, to be the third well-defined allotrope of carbon.

The fullerenes promise to have synthetic, pharmaceutical, and industrial applications. Derivatives have been found to exhibit fascinating electrical and magnetic behavior, in particular superconductivity and ferromagnetism.

Structures

All 60 atoms in fullerene-60 are equivalent and lie on the surface of a sphere distributed with the symmetry of a truncated icosahedron. The molecule was named after R. Buckminster Fuller, the inventor of geodesic domes, which conform to the same underlying structural formula.

Chemistry

Fullerene-60 behaves as a soft electrophile, a molecule that readily accepts electrons during a primary reaction step. It can accept three electrons readily and perhaps even more. The molecule can be multiply hydrogenated, methylated, ammoniated, and fluorinated.

Superconductivity

On exposure of C_{60} to certain alkali and alkaline earth metals, exohedrally doped crystalline materials are produced that exhibit superconductivity at relatively high temperatures (10–33 K).

Previously only metallic and ceramic materials exhibited superconductivity at temperatures much greater than a few kelvins. This discovery has opened the field of superconductivity to a different range of substances—in this case, molecular superconductors.

Nanoparticles and Nanotubes

The discovery that graphite networks (single sheets of hexagonally interconnected carbon atoms) can close readily has revolutionized general understanding of certain types of graphitic materials.

Carbon microparticles can spontaneously rearrange at high temperatures to form onion-like structures in which the concentric shells are fullerene or giant fullerenes. This phenomenon reveals the dynamics of carbon “melting.”

Most importantly, carbon nanofibers consisting of concentric graphene tubes can form. These structures are essentially elongated giant fullerenes and apparently form quite readily. They will be significant in the production of carbon-fiber composite materials.

Applications

The properties of fullerene materials that have been determined suggest that there is likely to be a wide range of areas in which the fullerenes or their derivatives will have uses. The facility for acceptance and release of electrons suggests a possible role as a charge carrier in batteries.

Fullerene nanotubes, tiny, tubular carbon fibers, were recently cut into open-ended pipes for the first time. This allows them to be chemically manipulated for use in nanotechnologies and materials. The attachment of molecules to the ends of the pipes lets them serve as means of binding to other chemical groups or surfaces.

The properties of graphite suggest that lubricative as well as tensile and other mechanical properties of the fullerenes are worthy of investigation. Liquid solutions exhibit excellent properties of optical harmonic generation. The high temperature at which superconducting behavior is observed suggests possible applications in microelectronics devices, as does the detection of ferromagnetism in other fullerene derivatives.

Full-Film Lubrication

A type of lubrication wherein the solid surfaces are separated completely by an elastohydrodynamic fluid film. See also *elastohydrodynamic lubrication* and *lubrication regimes*.

Fully Killed Steel

Steel that is fully deoxidized, mainly by silicon but also manganese, aluminum or titanium as appropriate.

Fully Penetrating Weld

A weld in which there is complete fusion through the thickness including the root.

Fulminates

Explosives used in percussion caps and detonators because of their sensitivity. They may be called *cap powder* in cartridge caps and detonators when used for detonating or exploding artillery shells. *Mercury fulminate*, a gray or brown, sandy powder, is the basis for many detonating compositions. It is made by the action of nitric acid on mercury and alcohol and is 10 times more sensitive than picric acid. It may be mixed with potassium chlorite and antimony sulfide for percussion caps. The fulminates may be neutralized with a sodium thiosulfate. The azides are a group of explosives containing no oxygen. They are compounds of hydrogen or a metal and a monovalent N_3 radical. *Hydrogen azide*, HN_3 , or *azoic acid*, and its sodium salt are soluble in water. *Lead azide* is used as a substitute for fulminate detonators. It is much more sensitive than mercury fulminate and in large crystals is subject to spontaneous explosion, but it is precipitated as a 93% pure product to suppress crystal formation and to form a free-flowing powder less sensitive to handling. Lead azide detonators for use in coal mining have *copper detonators*; for all other blastings *aluminum caps* are used.

Functional Group

A chemical radical or structure that has characteristic properties; examples are hydroxyl and carboxyl groups.

Functionality

The average number of reaction sites on an individual polymer chain.

Fungus Resistance

The resistance of a material to attack by fungi in conditions promoting their growth.

Furan Resins

Dark-colored thermosetting resins available primarily as liquids ranging from low-viscosity polymers to thick, heavy syrups,

which cure to highly cross-linked, brittle substances. Made primarily by polycondensation of furfural alcohol in the presence of strong acids, sometimes in combination with formaldehyde or furfuraldehyde.

Furfural

Also known as furfuraldehyde, furol, and pyromucaldehyde, furfural is a yellowish liquid with an aromatic odor, soluble in water and in alcohol, but not in petroleum hydrocarbons. On exposure, it darkens and gradually decomposes. Furfural occurs in different forms in various plant life and is obtained from complex carbohydrates known as pentosans, which occur in such agricultural wastes as cornstalks, corncobs, straw, oat husks, peanut shells, bagasse, and rice. Furfural is used for making synthetic plastics, as a plasticizer in other synthetic resins, as a preservative in weed killers, and as a selective solvent especially for removing aromatic and sulfur compounds from lubricating oils. It is also used for the making of butadiene, adiponitrile, and other chemicals.

Various derivatives of furfural are not used, and these, known collectively as furans, are now made synthetically from formaldehyde and acetylene, which react to form butyl neddole.

The *Tygon resins* are furfural resins used for brush application as protective coatings for such purposes as chemical tank linings. They cure by self-polymerization, will withstand temperatures to 350°F (177°C), and are resistant to acids, alkalis, alcohols, and hydrocarbons.

Furane plastics have high adhesion and chemical resistance, but they do not have high dielectric strength, and are black or dark in color. They are used for pipe, fittings, and chemical equipment parts and for adhesives and coatings.

Furfural Resins

A dark-colored synthetic resin of the thermosetting variety obtained by the condensation of furfural with phenol or its homologs. It is used in the manufacture of molding materials, adhesives, and impregnating varnishes. Properties include high resistance to acids and alkalis.

Furnace

A vessel or chamber in which a reaction or heat treatment occurs at a considerably elevated temperature, for example, blast furnace and annealing furnace. For lower temperatures "oven" tends to be favored although there are obvious exceptions such as coke oven. There is a large variety of furnaces. Heating may be any fuel including gas, oil, and electricity. The atmosphere may be air, combustion products, controlled (with respect to, for example, its oxidation or carbonization characteristics), or vacuum. The charger may be inserted from above, the end or the side, by hand, by a charging machine or on a rail car hearth. The charger may remain stationary or move forward progressively. See *rotary hearth* and *walking beam*.

Furnace Brazing

A mass-production *brazing* process in which the filler metal is preplaced on the joint, then the entire assembly is heated to brazing temperature in a furnace. Usually, a protective furnace atmosphere is required, and wetting of the joint surfaces is accomplished without using a brazing flux.

F

Furnace Soldering

A soldering process in which the parts to be joined are placed in a furnace heated to a suitable temperature.

Fuse

(1) A length of wire, or similar, in a suitable insulating and heat-resistant carrier that is installed in electrical circuits to protect the circuit if an excessive current is drawn. The size of the fuse wire is selected to match the maximum continuous current limit. A surge fuse has a similar function but is intended to protect against short-term excursions to high current. (2) Generally, to melt.

Fused Coating

A metallic coating (usually tin or solder alloy) that has been melted and solidified, forming a metallurgical bond to the basis metal.

Fused Silica

A glass made either by flame hydrolysis of silicon tetrachloride or by melting silica, usually in the form of granular quartz.

Fused Spray Deposit

A self-fluxing spray deposit which is deposited by conventional *thermal spraying* and subsequently fused using either a heating torch or a furnace. The coatings are usually made of nickel and cobalt alloys to which hard particles, such as tungsten carbide may be added for increased wear resistance.

Fused Zone

See preferred terms *fusion zone*, *nugget*, and *weld interface*.

Fusible Alloys

A group of binary, ternary, quaternary, and quinary alloys containing bismuth, lead, tin, cadmium, and indium. The term "fusible alloy" refers to any of more than 100 alloys that melt at relatively low temperatures, that is, below the melting point of tin-lead solder (183°C or 360°F). The melting points of these alloys range as low as 47°C (116°F).

Fusible alloys are those with melting points below the boiling point of water (100°C). They are used as binding plugs in automatic sprinkler systems, for low-temperature boiler plugs, for soldering pewter and other soft metals, for tube bending, and for casting pattern and many ornamental articles and toys. They are also used for holding optical lenses and other parts for grinding and polishing. They consist generally of mixtures of lead, tin, cadmium, and bismuth. The general rule is that an alloy of two metals has a melting point lower than that of either metal alone. By adding still other low-fusing metals to the alloy a metal can be obtained with almost any desired low melting point.

Newton's metal, used as a solder for pewter, contains 50% bismuth, 25% cadmium, and 25% tin. It melts at 95°C, and will dissolve in boiling water. Lipowitz alloy, another early metal, contains 3 parts cadmium, 4 tin, 15 bismuth, and 8 lead. It melts at 70°C, is very ductile, and takes a fine polish. It was employed for casting fine ornaments, but now has many industrial uses. A small amount of indium increases the brilliance and lowers the melting point 1.45°C for each 1% of indium up to a maximum of 18%. Wood's alloy, or Wood's fusible metal, was the first metal used for automatic

sprinkler plugs. It contained 7–8 parts bismuth, 4 lead, 2 tin, and 1–2 cadmium. It melts at 71°C, and this point was adopted as the operating temperature of sprinkler plugs in the United States; in England it is 68°C. The alloy designated as Wood's metal contains 50% bismuth, 25% lead, 2.5% tin, and 12.5% cadmium. It melts at 70°C.

Cerrobend, or Bendalloy, is a fusible alloy for tube bending that melts at 71°C. Cerrocast is a bismuth–tin alloy with pouring range of 138°C–170°C, and shrinkage of only 0.0025 cm/cm, used for making pattern molds. Cerrosafe, or Safalloy, is a fusible metal used for toy casting sets, as the molten metal will not burn wood or cause fires. Alloys with very low melting points are sometimes used for this reason for pattern and toy casting. A fusible alloy with a melting point at 60°C contains 26.5% lead, 13.5% tin, 50% bismuth, and 10% cadmium. These alloys expand on cooling and make accurate impressions of the molds.

The Tempil pellets are alloy pellets made with melting points in steps of –10.8°C, 10°C, and 37.7°C for measuring temperatures from 45°C to 1371°C. The Semalloy metals cover a wide range of fusible alloys with various melting points. Semalloy 1010 with a melting point at 47°C can be used where the melting point must be below that of thermoplastics. It contains 45% bismuth, 23% lead, 19% indium, 8% tin, and 5% cadmium. Semalloy 1280, for uses where the desired melting is near the boiling point of water, melts at 96°C. It contains 52% bismuth, 32% lead, and 16% tin.

Fusible Core

A core for injection molding manufactured from a low melting temperature alloy.

Fusible Insert (of Weld)

A preplaced filler having specific dimensions to locate snugly in the root of a joint to be made from one side. It is intended to be fully fused to become an integral part of the joint and is not normally machined following welding. Same as *consumable insert*.

Fusible Plug

A plug in the wall of a pressure vessel that is intended to melt and release the pressure if an excessive temperature is reached.

Fusing

The melting of a metallic coating (usually electrodeposited) by means of a heat-transfer medium, followed by solidification.

Fusion

In a nuclear reaction, the joining of light elements to form heavy elements with associated energy release.

Fusion (Plastics)

In vinyl dispersions, the heating of a dispersion to produce a homogeneous mixture.

Fusion (Welding)

The melting together of filler metal and base metal (substrate), or of base metal only, which results in coalescence. See also *depth of fusion*.

Fusion Cutting/Sawing

Same as *friction cutting/sawing*.

Fusion Face

A surface of the base metal which will be melted during welding.

Fusion Penetration (of Weld)

Same as *depth of fusion*.

Fusion Spray (Thermal Spraying)

The process in which the coating is completely fused to the base metal, resulting in a metallurgically bonded, essentially void free coating.

Fusion Welding

Any welding process in which the filler metal and base metal (substrate), or base metal only, are melted together to complete the weld.

Fusion Zone

The area of base metal melted as determined on the cross section of a weld.

Fuzz

Accumulation of short, broken filaments after passing glass strands, yarns, or rovings over a contact point. Often, weighted and used as an inverse measure of abrasion resistance.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

Gadolinium

A metallic element, one of the rare earth group.

Gag

A metal spacer inserted so as to render a floating tool or punch inoperative.

Gage

(1) The thickness of sheet or the diameter of wire. The various standards are arbitrary and differ with regard to ferrous and nonferrous products as well as sheet and wire. (2) An aid for visual inspection that enables an inspector to determine more reliably whether the size or contour of a formed part meets dimensional requirements. (3) An instrument used to measure thickness or length. (4) *Gauge* (United States).

Gagger

In foundry practice, an irregularly shaped piece of metal used for reinforcement and support in a sand mold.

Galena

Lead sulfide (PbS) particularly as the naturally occurring ore.

Gall

To damage the surface of a powder-metallurgy compact or die part, caused by adhesion of powder to the die cavity wall or a punch surface.

Galling

(1) A condition whereby excessive friction between high spots results in localized welding with subsequent *spalling* and a further roughening of the rubbing surfaces of one or both of two mating parts. (2) A severe form of scuffing associated with gross damage to the surfaces or failure. Galling has been used in many ways in tribology; therefore, each time it is encountered, its meaning must be ascertained from the specific context of the usage. See also *scoring* and *scuffing*.

Gallium

An elementary metal, symbol Ga, gallium is silvery white, resembling mercury in appearance but having chemical properties more nearly like aluminum. It melts at 30°C and boils at 2403°C, and this wide liquid range makes it useful for high-temperature thermometers. Like bismuth, the metal expands on freezing, and the expansion amounting to about 3.8%. Pure gallium is resistant to mineral acids and dissolves with difficulty in caustic alkali. Commercial gallium

has a purity of 99.9%. In the molten state, it attacks other metals, and small amounts have been used in Pb–Sn solders to aid wetting and decrease oxidation, but it is expensive for this purpose.

Gallium alloys readily with most metals at elevated temperatures. It alloys with tin, zinc, cadmium, aluminum, silver, magnesium, copper, and others. Tantalum resists attack up to 450°C and tungsten to 800°C. Gallium does not attack graphite at any temperature and silicon-based refractories are satisfactory up to about 1000°C.

Applications

Ga–Sn alloy has been used when a low-melting metal is needed. It is also used in rectifiers to operate to 316°C. The material has high electron mobility. This material in single-crystal bars is produced for lasers and modulators.

GaAs is an interesting new material because both gallium and arsenic are available in the state of extreme purity required for semiconductor applications and because the finished gallium arsenide (GaAs) in the proper state of purity can be used in transistors at high frequencies and high temperatures.

Another device using GaAs is a tunnel diode. Basically, a tunnel diode is a heavily doped junction diode that displays a quantum-mechanical tunneling effect under forward bias. This effect leads to an interesting negative resistance effect. Several applications for tunnel diodes are replacement for phase-locked oscillators, switching circuits, frequency-modulated transmitter circuits, and amplifiers.

GaAs is also used in increasing quantities for solar cells. A *pad-dle wheel* satellite in orbit demonstrates a dramatic commercial application of solar batteries. The NASA Deep Space 1 probe has a unique lens system that will enable its solar panels to generate power from a solar-cell area 1/16th the size of conventional silicon devices. A pair of solar-array wings uses refractive Fresnel lenses to concentrate light onto the cells; thus, less material is required. The panels are critical to the mission. They supply power not only for electronics but for the electric propulsion system of the vehicle as well. Each of the 5232 × 1600 mm GaAs-based array wings will produce 1.3 kW. The light-concentrating Fresnel lenses are silicon with a thin glass coating. Although more expensive per unit area than conventional silicon arrays, the more efficient (at 23%) multijunction GaAs cells further reduce the required solar-cell area, which, in turn, cut spacecraft size and mass. Net result: cost is half that of conventional planar panels.

In addition to GaAs, several gallium compounds have found application in the semiconductor field. GaO has been used for vapor-phase doping of other semiconductor materials, and the oxide and halides have application in epitaxial growth of GaAs and gallium phosphide (GaP). Gallium itself has been used as a dopant for semiconductors. Gallium ammonium chloride has been used in plating baths for the electrodeposition of gallium onto whisker wires used as leads for transistors.

GaSe, GaSc, GaI₃, and other compounds are also used in electronic applications.

A new solar cell being developed boasts 50% more power than traditional designs. The new cells, based on the two-junction,

G

Ga-In-P on GaAs technology, also have a longer life and are more resistant to radiation than silicon-based cells. This makes them well suited for communication satellites. (Silicon solar cells lose half their efficiency after 5 years in space.)

Other gallium alloys are suitable as dental alloys, and gallium is used in gold-platinum-indium alloys for dental restoration. Because of its low vapor pressure, gallium is being used as a sealant for glass joints in laboratory equipment, particularly mass spectrometers. Certain alloys (principally with cadmium and zinc) are used as cathodes in specialized vapor-arc lamps. Hard gallium alloys are used as low-resistance contact electrodes for bonding thermocouples and other wires to ferrites and semiconductors.

A new generation of transistors based on gallium nitride promises to deliver up to 100 times more power at microwave frequencies than current semiconductors. Tests have shown gallium nitride transistors with an output of up to 2.2 W/mm at a frequency of 4 GHz. This compares with about 1 W/mm at 10 GHz for GaAs transistors. By combining four devices, it may be possible to make transistors with an output power of 12.5 W/mm, with each device 2 mm long, on a monolithic integrated circuit to make a chip with an output power of 100 W at a frequency of 10 GHz.

The crystal from which the chips are made is grown on a heat sink made of either silicon carbide or sapphire (Al_2O_3). Instead of doping, in which small amounts of another material are added to the crystal, the researchers chose another method. In this technology, a thin layer of gallium aluminum nitride is placed on top of a base of gallium nitride. The bond between the two layers places a strain on the upper layers, which enables free electrons to flow into the gallium nitride layer, producing the holes that make it a semiconductor.

Applications could include military radar, portable satellite phones, and satellite transmitters. The high-power transistors may also save money. Satellites equipped with the devices could operate in higher orbits. This could usher the way for fewer satellites flying higher above the earth to give the same ground coverage.

The principal use of gallium is in the manufacture of semiconducting compounds. More than 90% of the gallium consumed in the United States is used for optoelectronic devices and integrated circuits. Optoelectronic devices—light-emitting diodes (LEDs), laser diodes, photodiodes, and solar (photovoltaic) cells—take advantage of the ability of GaAs to convert electrical energy into optical energy, and vice versa. An LED, which is a semiconductor that emits light when an electric current is passed through it, consists of layers of epitaxially grown material on a substrate. These epitaxial layers are normally gallium aluminum arsenide (GaAlAs), GaAs phosphide (GaAsP), or indium GaAsP (InGaAsP); the substrate material is either GaAs or GaP. Laser diodes operate on the same principle as LEDs, but they convert electrical energy to a coherent light output. Laser diodes principally consist of an epitaxial layer of GaAs, GaAlAs , or InGaAsP on a GaAs substrate. Photodiodes are used to detect a light impulse generated by a source, such as an LED or laser diode, and convert it to an electrical impulse. Photodiodes are fabricated from the same materials as LEDs. GaAs solar cells have been demonstrated to convert 22% of the available sunlight to electricity, compared with about 16% for silicon solar cells.

Although ICs currently represent a smaller share of the GaAs market than optoelectronic devices, they are important for military and defense applications. Two types of ICs are produced commercially: analog and digital. Analog ICs are designed to process signals generated by military radar systems, as well as those generated by satellite communications systems. Digital ICs essentially function as memory and logic elements in computers.

Nonsemiconducting applications include the use of gallium oxide for making single-crystal garnets—such as gallium gadolinium

garnet (GGG), which is used as the substrate for magnetic domain (bubble) memory devices. Small quantities of metallic gallium are used for low-melting-point alloys, for dental alloys, and as an alloying element in some magnesium, cadmium, and titanium alloys. Gallium is also used in high-temperature thermometers and as a substitute for mercury in switches. Gallium-based superconducting compounds, such as GaV_3 , have also been developed.

Galvanic Anode

A metal that, because of its relative position in the galvanic series, provides *sacrificial protection* to metals that are more noble in the series, when coupled in an electrolyte. See also *cathodic protection*.

Galvanic Cell

(1) A cell in which chemical change is the source of electrical energy. It usually consists of two dissimilar conductors in contact with each other and with an electrolyte or of two similar conductors in contact with each other and with dissimilar electrolytes. (2) A cell or system in which a spontaneous oxidation-reduction reaction occurs, the resulting flow of electrons being conducted in an external part of the circuit. See the term *cathodic protection*.

Galvanic Corrosion

Corrosion associated with the current of a galvanic cell consisting of two dissimilar conductors in electrolyte or two similar conductors in dissimilar electrolytes. Where the two dissimilar metals are in contact, the resulting reaction is referred to as couple action.

Galvanic Couple

A pair of dissimilar conductors, commonly metals, in electrical contact. See also *galvanic corrosion*.

Galvanic Couple Potential

See *mixed potential*.

Galvanic Current

The electric current that flows between metals or conductive nonmetals in a *galvanic couple*.

Galvanic Series

A list of metals and alloys arranged according to their relative corrosion potentials in a given environment. Compare with *electromotive force series*.

Galvanized Steel and Iron

Galvanizing is the process of coating irons and steels with zinc for corrosion protection. The zinc may be applied by immersing the substrate in a bath of the molten metal (hot-dip galvanizing), by electroplating the metal on the substrate (*electrogalvanizing*), or by spraying atomized particles of the metal onto otherwise finished parts. The zinc protects the substrate in two ways: (1) as a barrier to atmospheric attack and (2) galvanically, that is, if the coating is broken, exposing the substrate, the coating will corrode sacrificially or in preference to the substrate.

Both hot-dip galvanizing and electrogalvanizing are continuous processes applied in the production of galvanized steel, and the coating may be applied on one or both sides of the steel. In the case of hot-dip galvanized steel, the zinc at the steel face alloys with about 25% iron from the steel. Iron alloying decreases progressively to a region that is 100% zinc. Electrogalvanized steel typically has a more homogeneous but thinner coating of pure zinc and is somewhat more formidable than the hot-dip variety.

A spangled surface has long been characteristic of traditional hot-dip galvanized steel. Although that effect can be minimized, concern by automakers that the spangles might show through on painted external body panels gave rise to the development of *Zincrometal* in the early 1970s and increased use of electrogalvanized steel.

The American Iron and Steel Institute lists eight types of galvanized steel for auto applications in addition to Zincrometal. Five are of the hot-dip variety: (1) regular and minimum spangle, (2) fully coated but one side having a substantially lower weight, or thickness, of zinc than the other; (4) differentially zinc-iron-coated (same as differentially zinc coated except that the side with a thin coating is heat treated or wiped to produce a fully alloyed zinc-iron coating; and (5) one-side-coated (one side is zinc-free). The three types of electrogalvanized sheet steels are (1) electrolytic flash-coated [0.10–0.20 oz/ft² (30–60 g/m²) on both sides for minimal corrosion protection]; (2) electroplated zinc coated (coated on one side or both sides, the latter with equal differential coating weights, with as much as 0.65 oz/ft² (200 g/m²) total coating) and (3) electroplated iron-zinc coated (coated on one or both sides, the latter with equal or differential coating weights, by simultaneous electroplating of zinc and iron to form an alloy coating).

Galfan

Another two-side-coated hot-dip galvanized steel. The coating with 95% zinc and 5% aluminum and mischmetal is said to provide superior corrosion resistance compared to conventional galvanized steels in rural, marine, and severe-marine atmospheres.

Galvanizing

Galvanizing is the process of coating irons and steels with zinc for corrosion protection. From the standpoint of barrier protection alone, a coating weight of 400 g/m² on sheet steel will provide a service life of about 30 years in rural atmosphere and about 5 years in severe industrial atmosphere.

Hot dipping is widely practiced with mild steel sheet for garbage cans and corrugated sheets for roofing, sheeting, culverts, and iron pipe and with fencing wire. The electroplating method is also used for wire, as well as for applications requiring deep drawing. An alloy layer does not form; hence, the smooth electroplated coating does not flake in the drawing die.

It can be achieved by a hot-dip process, that is, immersion in molten zinc at about 450°C beneath a molten zinc chloride flux. The relatively thick coating comprises a zinc outer layer and a zinc iron diffusion layer at the interface. It is strongly bonded to the steel and is particularly suitable for substantial sections for structural applications. Electroplating or electrogalvanizing provides a thin or more accurately controlled coating suitable for smaller precision items. Metal spraying can offer a range of thicknesses and it can be applied on site if necessary, but the adhesion to the steel is critically dependent on the quality of preparation and application. Sherardizing involves baking components in zinc powder at just below the 419°C melting point of zinc to promote the formation of a thin diffusion coating. The term cold galvanizing is sometimes used for the

application of paints containing a high proportion of metallic zinc particles. It is claimed that the quantity of zinc and zinc particles and the substrate are in sufficiently good electrical contact to provide some cathodic protection.

Galvanizing Embrittlement

The embrittlement of steel resulting from the heating involved during hot-dip galvanizing at about 450°C. A form of *strain age hardening*.

Galvanneal

To produce a zinc-iron alloy coating on iron or steel by keeping the coating molten after hot-dip galvanizing until the zinc alloys completely with the basis metal.

Galvanometer

An instrument for indicating or measuring a small electric current by means of a mechanical motion derived from electromagnetic or electrodynamic forces produced by the current.

Galvanostatic

An experimental technique whereby an *electrode* is maintained at a constant current in an *electrolyte*.

Gamma

The Greek alphabetical reference to various phases in alloy systems, particularly gamma iron-austenite. See *steel*.

Gamma Iron

The face-centered cubic form of pure iron, stable from 910°C to 1400°C (1670°F to 2550°F).

Gamma Loop

The closed loop of the austenitic (i.e., gamma) region of iron chromium alloys.

Gamma Radiation

The electromagnetic radiation emitted by some radioactive materials as a result of their nuclear activity.

Gamma Ray

A high-energy photon, especially as emitted by a nucleus in a transition between two energy levels. It is similar to x-rays but of a nuclear origin; camera rays have a range of wavelengths from about 0.0005 to 0.14 nm. See the term *electromagnetic radiation*.

Gamma-Ray Spectrometry

See *gamma-ray spectroscopy*.

Gamma-Ray Spectroscopy

Determination of the energy distribution of γ -rays emitted by a nucleus. This is also known as *gamma-ray spectrometry*.

G

Gamma Structure

Structurally analogous phases or electron compounds having ratios of 21 valence electrons to 13 atoms. This is generally a large, complex cubic structure.

Gamma Transition

See *glass transition*.

Gang Milling

Milling with several cutters mounted on the same arbor or with workpieces similarly positioned for cutting either simultaneously or consecutively during a single setup.

Gang Slitter

A machine with a number of pairs of rotary cutters spaced on two parallel shafts, used for *slitting* metal into strips or for trimming the edges of sheets.

Gangue

The worthless portion of an ore that is separated from the desired part before smelting is commenced.

Ganister

A siliceous sandstone used as an acidic furnace lining.

Gap (Composites)

(1) In filament winding, the space between successive windings in which windings are usually intended to lay next to each other. It is the separation between fibers within a filament winding band. (2) The distance between adjacent plies in a lay-up of unidirectional tape materials.

Gap (in Welding)

(1) The minimum distance between surfaces to be joined as in root gap and the distance between the surfaces at the root. (2) The root opening in a weld joint. (3) The distance between the electrode and the workpiece over which an electric arc is struck, as an air gap.

Gap-Filling Adhesive

An adhesive subject to reduce shrinkage upon setting, used as a sealant.

Gap-Frame Press

A general classification of press in which the uprights or housings are made in the form of a letter C, thus making three sides of the die space accessible.

Garnet

A generic name for a related group of mineral silicates that have the general chemical formula $A_3B_2(SiO_4)_3$, where A is Fe^{2+} , Mn^{2+} ,

Mg, or Ca and B is Al, Fe^{3+} , Cr^{3+} , or Ti^{3+} . Garnet is used for coating abrasive paper or cloth, bearing pivots in watches, electronics, and the finer specimens for gemstones. The hardness of garnet varies from 6 to 8 Mohs (1360 Knoop), the latter being used for abrasive applications.

Garnets are trisilicates of alumina, magnesia, calcia, ferrous oxide, manganese oxide, or chromic oxide. Garnet-coated paper and cloth are preferred to quartz for the woodworking industries, because garnet is harder and gives sharper cutting edges, but Al_2O_3 is often substituted for garnet.

Synthetic garnets for electronic application are usually rare earth garnets with a rare earth metal substituted for the calcium and iron substituted for the aluminum and the silicate. Yttrium garnet is thus $Yt_3Fe_3(FeO_4)_3$. Yt-Al garnets of 3 mm diameter are used for lasers. Gadolinium garnet has been chosen for microwave use. Gd-Ga garnet made from GdO and GaO is used for computer bubble memories.

Gas

The state of matter in which a material is in a low density, highly fluid, and in a plastically compressible form.

Gas Atomization

An *atomization* process whereby molten metal is broken up into particles by a rapidly moving inert gas stream. The resulting particles are nearly spherical with attached satellites.

Gas Bearing

A journal or thrust bearing lubricated with gas.

Gas Brazing

See the preferred term *torch brazing*.

Gas Carbon Arc Welding

A carbon arc welding process variation that produces coalescence of metals by heating them with an electric arc between a single-carbon electrode and the work. Shielding is obtained from a gas or gas mixture.

Gas Carburizing

See *case hardening*.

Gas Chromatography

A separation method involving passage of a gaseous mobile phase through a column containing a stationary adsorbent phase; used principally as a quantitative analytical technique for volatile compounds. See also *chromatography*, *ion chromatography*, and *liquid chromatography*.

Gas Classification

The separation of a powder into its particle size fractions by means of a gas stream of controlled velocity flowing counterstream to the gravity-induced fall of the particles. The method is used to classify submesh-size particles.

Gas Classifier

A device for gas classification; it may be of laboratory size for quality control testing or of industrial capacity to accommodate powder production requirement.

Gas Constant

The constant of proportionality appearing in the equation of state of an ideal gas, equal to the pressure of the gas multiplied by its molar volume divided by its temperature. This is also known as *universal gas constant*. The constant, R , for 1 mol of gas is given by

$$pV = RT$$

where

p is the pressure
 V is the volume
 T is the temperature, absolute

In SI units, $R = 8.31 \text{ J/K/mol}$.

Gas Cutting

The use of oxygen/fuel gas torches, frequently oxyacetylene, for cutting metal, primarily steel. The general principle is that initially an intense gas/fuel flame heats the steel locally to its ignition temperature, 750°C – 825°C , and then an additional large quantity of high-pressure oxygen is introduced to cause combustion of the steel. The temperature is sufficient to produce a molten oxide slag that is vigorously ejected by the gas stream giving, under suitable conditions, a clean square edged cut. The equipment for manual use is somewhat similar to that used for gas welding except that the burner head has a pair of concentric nozzles, the outer providing the initial mixed fuel and the inner delivering the main oxygen blast. This main oxygen blast is usually controlled by a lever valve beneath the handgrip. The burner head, or multiple heads, may also be machine mounted and programmed to cut components of complex form with, if necessary, beveled edges. These machines are often termed profile cutters. See the preferred term *oxygen cutting*.

Gas Cyaniding

A misnomer for *carbonitriding*.

Gaseous Corrosion

Corrosion with gas as the only corrosive agent and without any aqueous phase on the surface of the metal. Also called *dry corrosion*. See also *hot corrosion* and *sulfidation*.

Gaseous Reduction

(1) The reaction of a metal compound with a reducing gas to produce the metal. (2) The conversion of metal compounds to metallic particles by the use of a reducing gas.

Gas Gouging

See the preferred term *oxygen gouging*.

Gas Holes

Holes in castings or welds that are formed by gas escaping from molten metal as it solidifies. Gas holes may occur individually, in clusters, or throughout the solidified metal.

Gasket Materials

These are any sheet material used for sealing joints between metal parts to prevent leakage, but gaskets may also be in the form of cordage or molded shapes. The simplest gaskets are waxed paper or thin copper. A usual requirement is the material will not deteriorate by the action of water, oils, or chemicals. Gasket materials are usually marketed under trade names. There are sheets of paper or fiber, 0.025–0.318 cm thick, coated to withstand oils and gasoline.

To resist high heat and pressure, there are sheets of metal coated with graphited asbestos, with a sheet metal punched with small tongues to hold the asbestos. There is felt impregnated with zinc chromate to prevent corrosion and electrolysis between dissimilar metal surfaces.

Foamed synthetic rubbers in sheet form, and also plastic impregnants, are widely used for gaskets. Some of the specialty plastics, selected for heat resistance or chemical resistance, are used alone or with fillers or as binders for fibrous materials.

A gasketing sheet to withstand hot oils and super octane gasolines is based on *Viton*, a copolymer of vinylidene fluoride and hexafluoropropylene. It contains about 65% fluorine, has a tensile strength of 13 MPa with elongation of 400%, and will withstand operating temperatures to 204°C with intermittent temperatures to 316°C .

Since the decline in the use of asbestos as a gasket material, several high-temperature alternatives have been developed. Aramid fibers, such as Akzo Fibers' *Twaron* and DuPont's *Kevlar*, contained within a nitrile-butadiene binder provide gaskets that will withstand temperatures up to 450°F (232°C). These products are also available coated with tetrafluoroethylene for use as braided packings. *Carbon-fiber gaskets* with the same binder will resist temperatures to 800°F – 900°F (427°C – 482°C). For temperatures 1100°F – 1200°F (593°C – 649°C), gaskets of graphite flakes compressed without a binder are used. *Grafoil* gaskets are made of *flexible graphite*. Intended for high-temperature uses, they also resist fire, acids, alkalis, salt solutions, halogens, and various organics. The *G-9900* gaskets rely on graphite fibers for heat resistance to 1004°F (540°C). They also resist saturated steam, hot oils, gasoline, aliphatic gases, and hydrocarbons. *Flexi-Braid 5000* gaskets are based on graphite ribbon braided yarn. They are used for packings in pumps and valves.

Gas Lubrication

A system of lubrication at which the shape and relative motion of the sliding surfaces cause the formation of a gas film having sufficient pressure to separate the surfaces. See also *pressurized gas lubrication*.

Gas Mass Spectrometry

An analytical technique that provides quantitative analysis of gas mixtures through the complete range of elemental and molecular gases.

Gas Metal Arc Cutting

An arc-cutting process used to sever metals by melting them with the heat of an arc between a continuous metal (consumable) electrode

G

and the work. Shielding is obtained internally from an externally supplied gas or gas mixture. This is also known as *metal inert gas welding*.

Gas Metal Arc Welding (GMAW)

An arc welding process that produces coalescence of metals by heating them with an arc between a continuous filler metal (consumable) electrode and the work. Shielding is obtained entirely from an externally supplied gas or gas mixture. Variations of the process include short-circuit arc GMAW, in which the consumable electrode is deposited during repeated short circuits, and pulsed arc GMAW, in which the current is pulsed. See also *globular transfer*, *short-circuiting transfer*, and *spray transfer*.

Gasoline

Gasoline is a colorless liquid hydrocarbon obtained in the fractional distillation of petroleum. It is used chiefly as motor fuel, but also as a solvent. Ordinary gasoline consists of the hydrocarbons between C_6H_{14} and $C_{10}H_{22}$, which distill off between the temperatures $69^\circ C$ and $174^\circ C$, usually having the light limit at heptane, C_7H_{16} , or octane, C_8H_{18} . The octane number is the standard of measure of detonation in the engine. Motor fuel, or the general name gasoline, before the wide use of high-octane gasolines obtained by catalytic cracking meant any hydrocarbon mixture that could be used as a fuel in an internal combustion engine by spark ignition without being sucked in as a liquid and without being so volatile as to cause imperfect combustion and carbon deposition. These included also mixtures of gasoline without call or benzol.

Gas Plating

Same as *vapor plating*.

Gas Pocket/Hole/Porosity

A cavity caused by entrapped gas during solidification.

Gas Pore (of Weld)

Relatively small internal voids formed by the entrapment of gases during solidification of the weld metal. Voids larger than about 1.5 mm are usually termed *weld zone* from contamination. Note that, strictly, this excludes processes in which shielding gases are produced by materials on, or in, the electrodes. Also see, *arc welding* and *gas metal arc welding*.

Gas Porosity

Five holes or pores within a metal that are caused by entrapped gas or by the evolution of dissolved gas during solidification.

Gas Regulator

See the preferred term *regulator*.

Gas Shielded Arc Welding

A general term used to describe gas metal arc welding, gas tungsten arc welding, and flux cored arc welding when gas shielding is employed. Typical gases employed include argon, helium, argon-hydrogen mixture, or carbon dioxide.

Gas Shielded Stud Welding

See *stud arc welding*.

Gassing

(1) Absorption of gas by a metal. (2) Evolution of gas from a metal during melting operations or upon solidification. (3) Evolution of gas from an electrode during electrolysis.

Gas Torch

See the preferred terms *welding torch* and *cutting torch*.

Gas Tungsten Arc Cutting

An arc-cutting process in which metals are severed by melting them with an arc between a single tungsten (nonconsumable) electrode and the work. Shielding is obtained from a gas or gas mixture.

Gas Tungsten Arc Welding (GTAW)

An arc welding process that produces coalescence of metals by heating them with an arc between a tungsten (nonconsumable) electrode and the work. Shielding is obtained from a gas or gas mixture. Pressure may or may not be used and filler metal may or may not be used.

Gas Welding

Any fusion welding process in which the heat source is provided by the combustion of a fuel gas with oxygen including air. Acetylene is the most common fuel gas but alternatives include propane, butane, coal gas, and hydrogen. In a typical handheld gas torch or blow-pipe, the two gases are mixed in the burner head and exit through a nozzle. A pair of screw valves to control gas supply is located close to the grip that is separated from the burner by metal tubing of length sufficient to avoid overheating the grip area and the operator. The torch is connected by substantial flexible rubber tubes to the gas supplies that may be cylinders or some more permanent installation. Additional filler may be introduced to the joint by a plain metal rod manipulated by the second hand of the operator.

See the preferred term *oxyfuel gas welding*.

Gate (Casting)

The portion of the runner in a mold through which molten metal enters the mold cavity. The generic term is sometimes applied to the entire network of connecting channels that conduct metal into the mold cavity. See the term *gating system*.

Gate (Plastics)

In injection and transfer molding of plastics, the orifice through which the melt enters the mold cavity. The gate can have a variety of configurations, depending on product design.

Gated Pattern

In foundry practice, a *pattern* that includes not only the contours of the part to be cast but also the *gates*.

Gate Mark

A surface discontinuity on a molded plastic part caused by the gate through which material enters the cavity.

Gathering

A forging operation that increases the cross section of part of the stock, usually a preliminary operation.

Gathering Stock

Any operation whereby the cross section of a portion of the forging stock is increased beyond its original size.

Gating System

The completed assembly of sprues, runners, and gates in a mold through which metal flows to enter casting cavity. The term is also applied to equivalent portions of the *pattern*.

Gauge (Gage in the United States)

(1) A measuring device. It may be an instrument or other device with some system for reading off dimensions, pressure, etc., or it may be a simple precision shape, for example, a feeler gauge. (2) A dimension such as thickness of sheet, wall thickness of tube, diameter of wire, and bar or spacing between tracks. There are numerous national and industry systems relating gauge numbers or letters to dimensions.

Gauge Length

The parallel length of a tensile or creep specimen on which elongation is measured.

Gauge Length

The original length of that portion of the specimen over which strength, change of length, and other characteristics are measured.

Gauss

The unit in the non-SI metric system of magnetic flux density defined as unit magnetic pole subjected to a force of 1° . 1 G (gauss) = 10^{-4} T (tesla).

Gear Cutting

Producing tooth profiles of equal spacing on the periphery, internal surface, or face of a workpiece by means of an alternate shear gear-form cutter or a gear generator.

Geared Press

A press whose main crank or eccentric shaft is connected by gears to the driving source.

Gear Hobbing

Gear cutting by use of a tool resembling a worm gear in appearance, having helically cutting teeth. In a single-thread hob, the rows of teeth

advance exactly one pitch as the hob makes one revolution. With only one hob, it is possible to cut interchangeable gears of a given pitch of any number of teeth within the range of the hobbing machine.

Gear Milling

Gear cutting with a milling cutter that has been formed to the shape of the tooth space to be cut. The tooth spaces are machined one at a time.

Gear Shaping

Gear cutting with a reciprocating gear-shaped cutter rotating in mesh with the work blank.

Gear Shaving

A finishing operation performed with a serrated rack or gear-like cutter in mesh with the gear, but with their axis skewed.

Geiger Counter

A device for detecting ionizing radiation. Various systems are employed but the common feature is that each ionizing event that is detected produces an electrical signal that may be recorded or emitted as noise.

Gel

A gel is a continuous solid network and enveloped in a continuous liquid phase; the solid phase typically occupies less than 10 vol% of the gel. Gels can be classified in terms of the network structure. The network may consist of agglomerated particles formed, for example, by destabilization of a colloidal suspension, a *house of cards* consisting of plates (as in a clay), fiber polymers joined by small crystalline regions, and polymers linked by covalent bonds.

In a gel, the liquid phase does not consist of isolated pockets, which is continuous. Consequently, salts can diffuse into the gel almost as fast as they disperse in a dish of free liquid. Thus, the gel seems to resemble a saturated household sponge, but it is distinguished by its colloidal size scale: the dimensions of the open spaces and of the solid objects constituting the network are smaller (usually much smaller) than a micrometer. This means that the interface joining the solid and liquid phases has an area on the order of 1000 m²/g of solid. As a result, the properties of a gel are controlled by interfacial and short-range forces, such as van der Waals, electrostatic, and hydrogen-bonding forces. Factors that influence these forces, such as introduction of salts or another solvent, application of an electric field, or changes in pH or temperature, affect the interaction between the solid and liquid phases. Variations in these parameters can induce huge changes in volume as the gel imbibes or expels liquid, and this phenomenon is exploited to make mechanical actuators or hosts for controlled release of drugs from gels. For example, a polyacrylamide gel (a polymer linked by covalent bonds) shrinks dramatically when it is transferred from a dish of water (a good solvent) to a dish of acetone (a poor solvent), because the polymer chains tend to favor contact with one another rather than with acetone, so the network collapses onto itself. Conversely, the reason that water cannot be gently squeezed out of such a gel (as from a sponge) is that the network has a strong affinity for the liquid, and virtually all of the molecules of the liquid are close enough to the solid-liquid interface to be influenced by those attractive forces.

G

Gelation

The most striking feature of a gel, which results from the presence of a continuous solid network, is elasticity: if the surface of a gel is displaced slightly, it springs back to its original position. If the displacement is too large, gels (except those with polymers linked by covalent bonds) may suffer some permanent plastic deformation, because the network is weak. The process of gelation, which transforms a liquid into an elastic gel, occurs with no change in color or transparency and no evolution of heat. It may begin with a change in pH that removes repulsive forces between the particles in a colloidal suspension or a decrease in temperature that favors crystallization of a solution of polymers or the initiation of a chemical reaction that creates or links polymers.

In many cases, both the liquid and solid phases of a gel are of practical importance (as in timed release of drugs or a gelatin dessert). More often (as in preparation of catalyst supports, chromatographic columns, or desiccants), it is only the solid network that is of use. If the liquid is allowed to evaporate from a gel, large capillary tension develops in the liquid, and the suction causes shrinkage of the network. The poorest network remaining after evaporation of the liquid is called a xerogel.

To maximize the ferocity of the dried product, the gel can be heated to a temperature and pressure greater than the critical point of the liquid phase, where capillary pressures do not exist. The fluid can then be removed with little or no shrinkage occurring. The resulting solid is called an aerogel, and the process is called supercritical drying.

Sol-Gel Processing

Sol-gel processing comprises a variety of techniques for preparing inorganic materials by starting with a sol, then gelling, drying, and (usually) firing. Many inorganic gels can be made from solutions of salts or metalorganic compounds and thus offers several advantages in ceramics processing: the reactants are readily purified; the compounds can be intimately mixed in the solution or sol stage; the sols can be applied as coatings, drawn into fibers, emulsified or spray-dried to make particles, or molded and gelled into shapes; xerogels can be sintered into dense solids at relatively low temperatures, because of their small pore size.

Gel (Polymers)

The initial jellylike solid phase that develops during the formation of a resin from a liquid. With respect to vinyl plastisols, a state between liquid and solid that occurs in the initial states heating, or upon prolonged storage. In general, gels have very low strengths and do not flow like a liquid. They are soft and flexible and may rupture under their own weight unless supported externally. In a cross-link thermoplastic, gel is the fraction of polymeric material present in the network.

Gelatin

A colorless to yellowish, water-soluble, tasteless colloidal hemicellulose obtained from bones or skins and used as a dispersing agent, sizing medium, coating for photographic films, and stabilizer for foodstuffs and pharmaceutical preparations. It is also flavored for use as a food jelly, and it is a high-protein, low-calorie foodstuff. While albumin has a weak, continuous molecular structure that is cross-linked and rigidized by heating, gelatin has an ionic or hydrogen bonding in which the molecules are brought together into

large aggregates, and it sets to a firmer solid. Gelatin differs from glue only in the purity. *Photographic gelatin* is made from skins. *Vegetable gelatin* is not true gelatin, but is algin from seaweed.

Collagen is the gelatin-bearing protein in bone and skins. The bone is dissolved in hydrochloric acid to separate out the calcium phosphate and is washed to remove the acid. The organic residue is called *osseine* and is the product used to produce gelatin and glue. About 25% of the weight of the bone is osseine, and the gelatin yield is about 65% of the osseine. One short ton (0.9 metric ton) of green bones, after being degreased and dried, yields about 300 lb (136 kg) of gelatin. When skins are used, they are steeped in a weak acid solution to swell the tissues so that the collagen may be washed out. The gelatin is extracted with hot water, filtered, evaporated, dried, and ground or flaked.

Gelatin Replica

A reproduction of a surface prepared in a film composed of gelatin. See also *replica*.

Gelation Time

(1) That interval of time, in connection with the use of synthetic thermosetting resins, extending from the introduction of a catalyst into a liquid adhesive system until the start of gel formation. (2) The time under application of load for a resin to reach a solid state.

Gel Coat

A quick-setting resin applied to the surface of a mold and gelled before *lay-up*. The gel coat becomes an integral part of the finished laminate and is usually used to improve surface and bonding.

Gelling Agent

See *thickener*.

Gel-Permeation Chromatography

See *size-exclusion chromatography*.

Gel Point

(1) The point at which a thermosetting system attains an infinite value of its average molecular weight. (2) The viscosity at which a liquid begins to exhibit pseudoelastic properties. This stage may be conveniently observed from the inflection point on a viscosity-time plot.

Gel Time

The period of time from the initial mixing of the reactants of a liquid material composition to the point in time when *gelation* occurs, as defined by a specific test method.

General Corrosion

(1) A form of deterioration that is distributed more or less uniformly over a surface. (2) *Corrosion* dominated by uniform thinning that proceeds without appreciable localized attack. See also *uniform corrosion*. (3) Corrosion acting over most or all of a specified area of

a component and producing a fairly even attack with no significant pitting and no associated cracking.

General Precipitate

A precipitate that is dispersed throughout the metallic matrix.

Geodesic

The shortest distance between two points on a surface.

Geodesic Isotenoid

Constant stress level in any given *filament* at all points in its path.

Geodesic-Isotenoid Contour

In filament-wound reinforced plastic pressure vessels, a dome contour in which the filaments are placed on geodesic paths so that the filaments exhibit uniform tensions throughout their length under pressure loading.

Gerber Diagram

See *fatigue*.

German Silver

Various alpha, single-phase alloys typified by 52% copper, 26% zinc, and 22% nickel with no silver content.

Germanium

A rare elemental metal, germanium (Ge) has a grayish white crystalline appearance and has great hardness of 6.25 Mohs. Its specific gravity is 5.35, and its melting point is 937°C. It is resistant to acids and alkalis. It has metallic-appearing crystals with diamond structure, gives greater hardness and strength to aluminum and magnesium alloys, and as little as 0.35% in tin will double the hardness. It is not used, commonly in alloys, however, because of its rarity and great cost. It is used chiefly as metal in rectifiers and transistors. An Au–Ge alloy, with about 12% germanium, has a melting point of 359°C and has been used for soldering jewelry.

Germanium is obtained as a by-product from flue dust of the zinc industry, or it can be obtained by reduction of its oxide from the ores and is marketed in small irregular lumps. Germanium crystals are grown in rods up to 3.49 cm in diameter for use in making transistor wafers. High-purity crystals are used for both *P* and *N* semiconductors. They are easier to purify and have a lower melting point than other semiconductors, specifically silicon.

Alloys

Two alloys of importance to the semiconductor industry are Ge–Al and Ge–Au. At 55 wt.% germanium, the Ge–Al system forms a eutectic that melts at 423°C. At 12 wt.% germanium, the Ge–Au system forms a eutectic that melts at 356°C. The two alloys are very useful in forming electrical contact systems for germanium transistors, diodes, and rectifiers. The Ge–Au system has been evaluated regarding its use for dental alloys because of its good dimensional stability upon cooling, thus allowing precision castings to be made.

The Ge–Si alloy system forms a continuous series of solid solutions. It has been explored quite extensively from the standpoint of its semiconductor characteristics.

Germanium has been investigated as a possible alloying agent for zirconium in the development of corrosion-resistant, high-strength zirconium alloys. Small additions of germanium are known to give increased hardness and strength to copper, aluminum, and magnesium. In addition, small quantities of germanium improve the rolling properties of some alloys and do not create any appreciable increase in production costs. Fundamental studies on the magnetic properties of Fe–Ge and Mn–Ge alloys have been made. These materials are ferromagnetic, as are the alloys UGe₂, PuGe, and CrGe.

Uses

The properties of germanium are such that there are several important applications for this element.

Semiconductor

During World War II, germanium was intensively investigated for its use in the rectification of microwaves for radar applications.

A major development in electronics occurred in 1948 with the invention of the transistor. This solid-state device, which was first made of germanium, had a profound influence on all electronic applications. The transistor captured the hearing aid and radio markets and then moved into industrial applications, such as computers and guidance and control systems for missile and antimissile systems. Transistors cover signal processing from dc to gigahertz frequencies, with power-handling capabilities from microwatts to hundreds of watts.

The development of germanium semiconductor technology quite closely parallels the development of the germanium transistor. In fabricating a transistor, a need arose for high-purity polycrystalline germanium to be used in the growth of single-crystal germanium since it was soon discovered that not only purity but also good crystal structure was required for good device performance. The growth processes for single crystals of germanium had to be developed. Several techniques have been extensively studied. Two of the most common are the Czochralski or Teal–Little method and zone leveling. The general method proceeds by allowing germanium to slowly freeze or crystallize onto a single crystal seed, which may be rotated and withdrawn from the melt. The growth (freeze) rate is controlled by a combination of the temperature of the melt and the amount of heat lost from the crystal by conduction up the seed and by radiation from its surfaces. Crystals from 0.16 to 15 cm in diameter have been grown by this process. Growth rates vary with diameter and desired crystal properties but are usually in the inches-per-hour range.

In the zone-leveling technique, or horizontal method, the seed and polycrystalline charge or ingot are usually loaded into a quartz boat. The boat and contents are then placed into the quartz tube of the zone leveler. With this technique, melting occurs on the leading edge of the molten zone, and freezing occurs on the trailing edge as the furnace is moved. Growth rates vary with crystal properties desired but are usually in the inches-per-hour range. The advantage of this process over the Teal–Little for germanium is the extremely uniform resistivity profile of the crystal due to the uniform mass of molten germanium and the growth process. The constant mass of molten germanium enables the ratio of dopant to germanium to remain the same, thus producing uniform resistivity.

In the fabrication of germanium devices, the single-crystal material must be sawed, lapped, or ground and then polished into thin-slice forms with flat, damage-free surfaces. Various techniques have

G

been developed to produce slices with these characteristics. Some of these are slicing with diamond wheels, grinding with diamond, or lapping with an abrasive slurry. These techniques induce damage in the form of microcracks and fissures, which must be removed by chemical, electrochemical, or chemical-mechanical polishing methods.

Two other growth techniques (modifications of melt growth) have been explored. One is dendritic growth, which depends on the growth characteristics of twinned crystals, and the other in shaped crystal growth, which is dependent on a shaped heat zone. Both techniques can produce thin ribbons of germanium with desired characteristics for some type of devices.

Vapor-phase crystal growth at temperatures well below the melting point is used for growing thin films or layers onto slices and is usually referred to as epitaxial growth. The primary advantage of gas-phase growth is that it allows doping impurities to be changed quite rapidly so that thin (micrometer range) layers of quite different resistivities can be grown sequentially.

Optoelectronics

Another use that surfaced as a result of the cost of material such as gallium arsenide and the inability to control its growth is the use of Czochralski- or Teal-Little-grown single-crystal germanium as a substrate for vapor-phase growth of GaAs and gallium arsenide phosphide (GaAsP) thin films used in some light-emitting diodes (LEDs). These devices have been used in digital displays for calculators, watches, and so on.

Infrared Optical Materials

Germanium lenses and filters have been used in instruments that operate in the infrared region of the spectrum. Windows and lenses of germanium are vital components of some laser and infrared guidance or detection systems. Glasses prepared with germanium dioxide have a higher refractivity and dispersion than do comparable silicate glasses and may be used in wide-angle camera lenses and microscopes.

Getter

(1) A special metal or alloy that is placed in a vacuum tube during manufacture and vaporized after the tube has been evacuated; when the vaporized metal condenses, it absorbs residual gases. (2) In powder metallurgy, a substance that is used in a sintering furnace for the purpose of absorbing or chemically binding elements or compounds from the sintering atmosphere that are damaging to the final product. (3) A reactive material enclosed in sealed vessels such as thermionic valves to scavenge the last trace of oxygen or other undesirable gases. The getter material forms, or is located, on a filament that is heated to incandescence after the vessel has been sealed. Various metals are used including magnesium, cerium, zirconium, and titanium.

Gettering Box

In powder metallurgy, a container for the getter substance that is readily accessible to the atmosphere and prevents contamination of the sintered product by direct contact.

Ghost Bands

Bands of ferrite within the ferrite/pearlite matrix of some wrought pearlitic steels. They are residual effect of casting segregation and usually contain high phosphorus.

Ghost Lines

Lines running parallel to the rolling direction that appear in a sheet-metal panel when it is stretched. These lines may not be evident unless the panel has been sanded or painted. Not to be confused with *leveler lines*.

Gibbs Free Energy

The thermodynamic function $\Delta G = \Delta H - T\Delta S$, where H is the enthalpy, T is the absolute temperature, and S is the entropy. This is also called *free energy*, free enthalpy, or the Gibbs function.

Gibbs Triangle

An equilateral triangle used for plotting composition in a ternary system.

Gibs

Guides or shoes that ensure the proper parallelism, squareness, and sliding fit between metal-forming press components such as the slide and the frame. They are usually adjustable to compensate for wear and to establish operating clearance.

Gilding

The application of gold leaf or sheet to a surface for decorative effect.

Gilding Metal

Brass with 90% copper and 10% zinc and no gold. It is similar in color to gold and is usually used in wrought bulk form rather than as a surface coating. It can also be treated to produce a brownish tint similar in appearance to bronze.

Gilsonite

A natural asphalt used for roofing, paving, floor tiles, storage battery cases, and coatings and for adding to heavy fuel oils. It is a lustrous, black, almost odorless, brittle solid, having a specific gravity of 1.10. Gilsonite is one of the purest asphalts and has high molecular weight. It is soluble in alcohol, turpentine, and mineral spirits.

Gilt

Silver or other metal that has been gilded, that is, surface with a thin layer of gold.

Girder

A beam for structural purposes, typically of I section to give maximum resistance to bending for a given weight, usually steel.

Glancing Angle

In materials characterization, the angle (usually small) between an incident x-ray beam and the surface of the specimen.

Glass

Glass, one of the oldest and most extensively used materials, is made from the most abundant of earth's natural resources—silica sand. For centuries considered as a decorative, fragile material suitable for only glazing and art objects, today glasses produced in thousands of compositions and grades for a wide range of consumer and industrial applications.

Composition and Structure

As just stated, the basic ingredient of glasses is silica (silicon dioxide), which is present in various amounts, ranging from about 50% to almost 100%. Other common ingredients are oxides of metals, such as lead, boron, aluminum, sodium, and potassium.

Unlike most other ceramic materials, glass is noncrystalline. In its manufacture, a mixture of silica and other oxides is melted and then cooled to a rigid condition. The glass does not change from a liquid to a solid at a fixed temperature but remains in a vitreous, noncrystalline state and is considered as a supercooled liquid. Thus, because the relative positions of the atoms are similar to those of liquids, the structure of glass has short-range order. However, glass has some distinct differences compared to a supercooled liquid. Glass has a 3D framework and the atoms occupy definite positions. There are covalent bonds present that are the same as those found in many solids. Therefore, there is a tendency toward an ordered structure in that there is present in glass a continuous network of strongly bonded atoms.

Properties and Processing

Glass is an amorphous solid made by fusing silica (silicon dioxide) with a basic oxide. Its characteristic properties are its transparency, its hardness and rigidity at ordinary temperatures, its capacity for plastic working at elevated temperatures, and its resistance to weathering and to most chemicals except hydrofluoric acid. The major steps in producing glass products are (1) melting and refining, (2) forming and shaping, (3) heat treating, and (4) finishing. The mixed batch of raw materials, along with broken or reclining glass, called cullet, is fed into one end of a continuous-type furnace where it melts and it remains molten at around 1499°C. Molten glass is drawn continuously from the furnace and runs in troughs to the working area, where it is drawn off for fabrication at a temperature of about 999°C. When small amounts are involved, glass is melted in pots.

Types of Glass

There are a number of general families of glasses, some of which have many of hundreds of variations in composition.

Soda-Lime Glasses

The soda-lime family is the oldest, lowest in cost, easiest to work, and most widely used. It accounts for about 90% of the glass used in this country. Soda-lime glasses have only fair to moderate corrosion resistance and are useful up to about 460°C, annealed, and up to 249°C, tempered. Thermal expansion is high and thermal shock resistance is low compared with other glasses. They are the glass of ordinary windows, bottles, and tumblers.

Lead Glasses

Lead or lead alkali glasses are produced with lead contents ranging from low to high. They are relatively inexpensive and are noted for

high electrical resistivity and high refractory index. Corrosion resistance varies with lead content, but they are all poor in acid resistance compared with other glasses. Thermal properties also vary with lead content. The coefficient of expansion, for example, increases with lead content. High lead grades are heaviest of the commercial glasses. As a group, lead classes are the lowest in rigidity. They are used in many optical components, for neon sign tubing, and for electric light bulb stems.

Borosilicate Glasses

Borosilicate glasses are most versatile and are noted for their excellent chemical durability, for resistance to heat and thermal shock, and for low coefficients of thermal expansion. There are six basic kinds. The low-expansion type is best known as the Pyrex brand ovenware. The low-electrical-loss types have a dielectric loss factor only second to fused silica and some grades of 96% silica glass. Sealing types, including the well-known Kovar, are used in glass-to-metal sealing applications. Optical grades, which are referred to as crowns, are characterized by high light transmission and good corrosion resistance. Ultraviolet-transmitting and laboratory apparatus grades are two other borosilicate-type glasses. Because of this wide range of types and compositions, borosilicate glasses find use in such products as sites and gauges, piping, seals to low-expansion metals, telescope mirrors, electronic tubes, laboratory glassware, ovenware, and pump impellers.

Aluminosilicate Glasses

These glasses are roughly three times more costly than borosilicate types, but are useful at higher temperatures and have greater thermal shock resistance. Maximum service temperature for annealed condition is about 649°C. Corrosion resistance to weathering, water, and chemicals is excellent, although acid resistance is only fair compared with other glasses. Compared to 96% silica glass, which it resembles in some respects, it is more easily worked and is lower in cost. It is used for high-performance power tubes, traveling wave tubes, high-temperature thermometers, combustion tubes, and stovetop cookware.

Fused Silica

Fused silica is 100% silicon dioxide. If naturally occurring, the glass is known as fused quartz. There are many types and grades of both glasses, depending on impurities present and manufacturing method. Because of its high purity level, fused silica is one of the most transparent glasses. It is also the most heat resistant of all glasses and it can be used up to 899°C in continuous service and to 1260°C for short-term exposure. In addition, it has outstanding resistance to thermal shock, maximum transmittance to ultraviolet, and excellent resistance to chemicals. Unlike most glasses, its modulus of elasticity increases with temperature. Because fused silica is high in cost and difficult to shape, its applications are restricted to such specialty applications as laboratory optical systems and instruments and crucibles for crystal growing. Because of the unique ability to transmit ultrasonic elastic waves with little distortion or absorption, fused silica is used in the delay lines in radar installations.

96% Silica Glass

These glasses are similar in many ways to fused silica. Although less expensive than fused silica, they are still more costly than most

G

other glasses. Compared to fused silica, they are easier to fabricate and have a slightly higher coefficient of expansion, about 30% lower thermal stress resistance, and a lower softening point. They can be used continuously up to 799°C. Uses include chemical glassware and windows and heat shields for space vehicles.

Phosphate Glass

Phosphate glass will resist the action of hydrofluoric acid and fluorine chemicals. It contains no silica, but is composed of P_2O_5 with some alumina and magnesia. It is transparent and can be worked like ordinary glass, but it is not resistant to water.

Sodium-Aluminosilicate Glass

These glasses are chemically strengthened and are used in premium applications, such as aircraft windshields. Molten salt baths are used as the strengthening process.

Industrial Glass

This is a general name usually meaning any glass molded into shape for product parts. The lime glasses are the most frequently used because of low cost, ease of molding, and adaptability to fired colors. For such uses as light lenses and condenser cases, the borosilicate heat-resistant glasses may be used.

Boric Oxide Glasses

These glasses are transparent to ultraviolet rays. The so-called invisible glass is a borax glass surface treated with a thin film of sodium fluoride. It transmits 99.6% of all visible light rays, thus casting back only slight reflection and giving the impression of invisibility. Ordinary soda and potash glasses will not transmit ultraviolet light. Glass containing 2%–4% ceric oxide absorbs ultraviolet rays and is also used for x-ray shields. Glass capable of absorbing high-energy x-rays or gamma rays may contain tungsten phosphate, while the glass used to absorb slow neutrons in atomic-energy work contains cadmium borosilicate with fluorides. The shields for rocket capsule radio antennas are made of 96% silica glass.

Optical Glass

Optical glass is a highly refined glass that is usually a flint glass of special composition, or made from rock crystal, used for lenses and prisms. It is cast, rolled, or pressed. In addition to the regular glass-making elements, silica and soda, optical glass contains barium, boron, and lead. The high-refracting glasses contain abundant silica or boron oxide. A requirement of optical glasses is transparency and freedom from color.

Plate Glass

This is any glass that has been cast or rolled into a sheet and then ground and polished. However, the good grades of plate glass are, next to optical glass, the most carefully prepared and the closest to perfect of all the commercial glasses. It generally contains slightly less calcium oxide and slightly more sodium oxide than window glass, and small amounts of agents to give special properties may be added, such as agents to absorb ultraviolet or infrared rays, but inclusions that are considered impurities are kept to a minimum. The largest use of plate glass is for storefronts and office partitions.

Plate glass is now made on a large scale on continuous machines by pouring on a casting table at a temperature of about 1000°C, smoothing with a roller, annealing, setting rigidly on a grinding table, and grinding to a polished surface.

Conductive Glass

This glass, which is employed for windshields to prevent icing and for uses where the conductive coating dissipates static charges, is plate glass with a thin coating of stannic oxide produced by spraying glass, at 482°C–704°C, with a solution of stannic chloride. Coating thicknesses are 50–550 nm, and the coating will carry current densities of 9.300 W/m² indefinitely. The coatings are hard and resistant to solvents. The light transmission is 70%–88% that of the original glass, and the index of refraction is 2.0, compared with 1.53 for glass.

Transparent Mirrors

These are made by coating plate glass on one side with a thin film of chromium. The glass is a reflecting mirror when the light behind the glass is less than in front and is transparent when the light intensity is higher behind the glass. Photosensitive glass is made by mixing submicroscopic metallic particles in the glass. When ultraviolet light is passed through the negative on the glass, it precipitates these particles out of solution, and since the shadowed areas of the negative permit deeper penetration into the glass than the high light areas, the picture is in three dimensions and in color. The photograph is developed by heating the glass to 538°C.

Other Glasses

Colored glasses: Made by adding small amounts of colorants to glass batches and are used in lamp bulbs, sunglasses, light filters, and signalware.

Opal glasses: Contain small particles dispersed in transparent glass. The particles disperse the light passing through the glass, producing an opalescent appearance.

Polarized glass for polarizing lenses: Made by adding minute crystals of tourmaline or peridot to the molten glass and stretching the glass while still plastic to bring the axes of the crystals into parallel alignment.

Porous glass: Made of silica sand, boric acid, oxides of alkali metals (sodium, potassium, etc.), and a small amount of zirconia. This glass has 500 times better resistance to alkali solution than has otherwise been achieved to date. The glass is made by first melting, with the heat treatment of 650°C–800°C, then separating into two phases, one composed mainly of silica and the other containing boric acid and alkali metal oxides; this is known as phase splitting. The boric acid–alkali oxides phase elutes in heat treatment, producing small holes that give porous glass its name. The glass is heat resistant, transmits gas, and permits adhesion of many substances to its surface. It is, therefore, used at high temperatures as a gas-separating membrane and as a carrier of various substances.

Oxycarbide Glass

This glass has been developed in which substituting carbon for oxygen or even nitrogen can create a whole new category of high-strength glasses. In a 1.0% carbon–glass system of Mg–Si–Al–O, Vickers hardness was increased significantly as well as glass transition temperature. The oxycarbide glass was prepared firing SiO_2 , Al_2O_3 , MgO, and SiC in a molybdenum crucible at 1800°C for 2 h.

Oxycarbide glass systems based on Si-metal-O-C and Al-metal-O-C are likely to exist and could potentially be used to produce refractory glasses. Controlled recrystallization of oxycarbides could lead to stable glass-ceramic matrices for ceramic-reinforced composites.

Products

The most common glass products are containers and flat glass. The latter is principally used in transportation and architecture. Flat glass is produced by the float process, developed in the 1950s, and considered one of the important technological achievements of the twentieth century.

Containers are largely made on automatic machines; some special pieces may be made by hand blowing into molds, and some very special ware may be made by the free or offhand blowing of a skilled glassblower.

Electric light bulb envelopes are molded on a special machine that converts a fast-moving ribbon of glass into over 10,000 bulbs/min.

Glass fibers are either continuous for reinforcement or discontinuous for insulation; see *glass fiber*.

Glass wool is most often made by spinning, or forcing molten glass centrifugally out of small holes (around 20,000) in the periphery of a rapidly rotating steel spinner, and attenuating the fibers by entrainment with gas burners. As the fibers fall to a conveyor, they are sprayed with a binder that preserves their open structure. The resulting glass wool mat is mainly composed of still air, which accounts for its excellent insulation properties.

Glass-Ceramics

A family of finer-grained crystalline materials made by a process of controlled crystallization from special glass compositions containing nucleating agents; glass-ceramics are sometimes referred to as nucleated glass, devitrified ceramic, or vitro ceramics. Because they are mixed oxides, different degrees of crystallinity can be produced by varying compositions and heat treatments. Some of the types produced are cellular foams, coatings, adhesives, and photosensitive compositions.

Glass-ceramics are nonporous and generally either opaque white or transparent. Although not ductile, they have much greater impact strength than commercial glasses and ceramics. However, softening temperatures are lower than those for ceramics, and they are generally not useful above 1093°C. Thermal expansion varies from negative to positive values depending on composition. Excellent thermal shock resistance and good dimensional stability can be obtained if desired. These characteristics are used to advantage in *heatproof* skillets and range tops. Like chemical glasses, these materials have excellent corrosion and oxidation resistance. They are electrical insulators and are suitable for high-temperature, high-frequency applications in the electronics field.

Pyroceram is a hard, strong, opaque-white nucleated glass with a flexural strength to above 206 MPa, a density of 2.4–2.62, a softening point at 1349°C, and high thermal shock resistance. It is used for molded mechanical and electrical parts, heat-exchanger tubes, and coatings. *Macor* is a machinable glass-ceramic. Axles for mechanisms that provide power in cardiac pacemakers have been chosen from Macor due to its chemical inertness and light weight. It is also used as welding fixtures and as welding nozzles. *Nucelite*, which is used for lining tanks, pipes, and valves, is nucleated glass. It has about four times the abrasion resistance of a hard glass, will

withstand sudden temperature differences of 649°C, and has high impact resistance. It also has high heat-transfer efficiency.

Applications

The first use of glass-ceramics was in radomes for supersonic missiles, where a radar-transmitting material with a combination of strength, hardness, temperature and thermal shock resistance, uniform quality, and precision finishing is required.

The second large-scale application is in “heatproof” skillets and saucepans, again taking advantage of the thermal shock resistance.

One of the products of potential interest to mechanical engineers is bearings for operation at high temperatures without lubrication or in corrosive liquids. Another is a lightweight, dimensionally stable honeycomb structure, which has promise for use in heat regenerators for gas turbines operating at high temperatures. Still a third possibility is precision gauges and machine tool parts whose dimensions do not change with temperature.

Bearings

Although metal bearings are perfectly satisfactory for most applications, there are conditions such as high temperature, dry (unlubricated) operation, and presence of corrosive media in which even the best metal bearings may perform poorly. Also, the metals that do perform best are expensive, difficult to fabricate, and heavy.

Since glass-ceramic bearings might be expected to be stable at high temperatures, resistant to oxidation and to corrosive conditions, as well as light in weight, a thorough evaluation of their characteristics is being made by a number of laboratories and bearing manufacturers. One of the surprising findings has been that glass-ceramic bearings can be finished almost as easily as steel bearings and in the same general type of equipment.

High-Temperature Heat Exchangers

The thermal shock resistance and dimensional stability of the low-expansion glass-ceramics make them useful in various kinds of heat exchangers. One interesting type has been developed for use in high-temperature turbine engines.

Precision Uses

As requirements for precision instruments and machines become more stringent, the gauges and machine tools required to make them must become still more precise and dimensions. If these are made of relatively high expansion metals such as steel, the dimensions vary with temperature.

Glass Cloth

Woven glass-fiber material. See also *scrim*.

Glass Electrode

A glass membrane electrode used to measure pH or hydrogen-ion activity.

Glass Fiber

Fine flexible fibers made from glass are used for heat and sound insulation, fireproof textiles, acid-resistant fabrics, retainer mats

G

for storage batteries, panel board, filters, and electrical insulating tape, cloth, and rope. Molten glass strings out easily into thread-like strands, and this spun glass was early used for ornamental purposes, but the first long fibers of fairly uniform diameter were made in England by spinning ordinary molten glass on revolving drums. The original fiber, about 0.003 cm in diameter, was called glass silk and glass wool, and the loose blankets for insulating purposes were called *navy wool*. The term navy wool is still used for the insulating blankets faced on both sides with flameproof fabric, employed for duct and pipe insulation and for soundproofing.

Glass fibers are now made by letting the molten glass drop through tiny orifices and blowing with air or steam to attenuate the fibers. The usual composition is that of soda-lime glass, but it may be varied for different purposes. The glasses low in alkali have high electrical resistance, whereas those of higher alkali are more acid resistant. They have very high tensile strengths, up to about 2757 MPa.

The standard glass fiber used in glass-reinforced plastics is a borosilicate type known as *E-glass*. The fibers spun as single glass filaments, with diameters ranging from 0.0005 to 0.003 cm, are collected into strands that are manufactured into many forms of reinforcement. E-glass fibers have a tensile strength of 3445 MPa. Another type, *S-glass*, is higher in strength, about one-third stronger than E-glass, but because of higher cost, 18 times more costly per pound vs. E-glass, its use is limited to advanced, higher-performance products.

Staple glass fiber is usually from 0.0007 to 0.0009 cm, is very flexible and silky, and can be spun and woven on regular textile machines. Glass-fiber yarns are marketed in various sizes and twists, in continuous or staple fiber, and with glass compositions varied to suit chemical or electrical requirements.

Halide glass fibers are composed of compounds containing fluorine and various metals such as barium, zirconium, thorium, and lanthanum. They appear to be promising for fiber-optic communication systems. Their light-transmitting capability is many times better than that of the best silica glasses now being used.

Glass-fiber cloth and glass-fiber tape are made in satin, broken twill, and plain weaves; satin-wear cloth is 0.02 cm thick weighing 0.24 kg/m². Glass cloth of plain weave of either continuous fiber or staple fiber is much used for laminated plastics. The usual thicknesses are from 0.005 to 0.058 cm in weights from 0.05 to 0.50 kg/m². Cloth woven of monofilament fiber in loose rovings to give better penetration of the impregnating resin is also used. Glass mat, composed of fine fibers felted or intertwined in random orientation, is used to make sheets and boards by impregnation and pressure. Fluffed glass fibers are tough, twisted glass fibers. For filters and insulation the cell withstands temperatures to 538°C. Chopped glass, consisting of glass fiber cut to very short lengths, is used as a filler for molded plastics. Translucent corrugated building sheet is usually made of glass-fiber mat with a resin binder. All these products, including chopped fiber, mat, and fabric preimpregnated with resin, and the finished sheet and board, are sold under a wide variety of trade names. Glass fiber bonded with a thermosetting resin can be preformed for pipe and other insulation coverings. Glass-fiber block is also available to withstand temperatures to 316°C. Glass filter cloth is made in twill and satin weaves in various thicknesses and porosities for chemical filtering. Glass belting, for conveyor belts that handle hot and corrosive materials, is made with various resin impregnations. Many synthetic resins do not adhere well to glass, and the fiber is sized with vinyl chlorosilane or other chemicals.

Four major principles should be recognized in using glass fibers as composite reinforcements. Mechanical properties depend on the

combined effect of the amount of glass-fiber reinforcement used and its arrangement in the finished composite. The strength of the finished object is directly related to the amount of glass in it. Generally speaking, strength increases directly in relation to the amount of glass. A part containing 80 wt% glass and 20 wt% resin is almost four times stronger than a part containing the opposite amounts of these two materials. Chemical, electrical, and thermal performance are influenced by the resin system used as a matrix. Materials selection, design, and production requirements determine the proper fabrication process to be used. Finally, the cost-performance value achieved in the finished composite depends on good design and judicious selection of raw materials and processes. See also *fiberglass*.

Glass Filament

A form of glass that has been drawn to a small diameter and extreme length. It is standard practice in the fiberglass industry to refer to a specific filament diameter by a specific alphabet designation. Fine fibers, which are used in textile applications, range from *D* (–6 μm) through *G* (–10 μm). Conventional plastics reinforcement, however, uses filament diameters that range from *G* to *T* (–24 μm).

Glass Filament Bushing

The units through which molten glass is drawn in making glass filaments.

Glass Finish

A material applied to the surface of a glass reinforcement to improve the bond between the glass and the plastic resin matrix.

Glass Flake

Thin, irregularly shaped flakes of glass used as a reinforcement in composites.

Glass Former

An oxide that forms a glass easily and also one that contributes to the network of silica glass when added to it.

Glass Paper

An abrasive material produced by bonding a layer of graded powdered glass to a strong paper backing. More useful for wood and similarly soft materials rather than metal.

Glass, Percent by Volume

The product of the specific gravity of a laminate and the percent glass by weight, divided by the specific gravity of the glass.

Glass Sand

Sand employed in glassmaking. Glass sands are all screened and usually washed, to remove fine grains and organic matter. Sand for first-quality optical glass should contain 99.8% SiO₂ and a maximum of 0.1 Al₂O₃ and 0.02 Fe₂O₃. *Potters' sand* is usually a good grade of glass sand of uniform grain employed for packing to keep the wares apart.

Glass Stress

In a filament-wound part, usually a pressure vessel, the stress calculated using the load and the cross-sectional area of the reinforcement only.

Glass Transition Temperature (T_g)

The temperature at which an amorphous polymer (or the amorphous regions in a partially crystalline polymer) changes from a hard and relatively brittle condition to a viscous or rubbery condition. In this temperature region, many physical properties, such as hardness, brittleness, thermal expansion, and specific heat, undergo significant rapid changes.

Glassy

A state or matter that is amorphous or disordered like a liquid in structure, hence capable of continuous composition variation and lacking a true melting point, but softening gradually with increasing temperature. Glasses of commerce are mainly complex silicates in chemical combination with numerous other oxidic substances, made by melting the source materials together, forming in various ways while fluid, and allowing to cool.

Glaze

(1) A ceramic coating matured to the glassy state on a formed ceramic article or the material or mixture from which the coating is made. (2) In tribology, a ceramic or other hard, smooth surface film produced by sliding. (3) The production of a hard smooth surface or the surface so formed. The term may be used of a surface that has itself become glazed as a result of some process or of material applied as a liquid or powder that is then heated to form a glaze over the substrate. (4) The installation of glass sheet into a framework of glazing bars.

Glazing

Glazing involves the application of finely ground glass, or glass-forming materials, or a mixture of both, to a ceramic body and then heating (firing) to a temperature where the material or materials melt, forming a coating of glass on the surface of the ware. Glazes are used to decorate the ware, to protect against moisture absorption, to give an easily cleaned, sanitary surface, and to hide a poor body color.

Glazes are classified and described by the following characteristics: surface, glossy or matte; optical properties, transparent or opaque; method of preparation, fritted or raw; composition, such as lead, tin, or boron; maturing temperatures; and color. Opaque glazes contain small crystals embedded in the glass, but special glazes in which a few crystals grow to recognizable size are called crystalline glazes. A glaze may be applied during the firing; such a glaze is called salt glaze. Common salt, NaCl, or borax, $\text{Na}_2\text{B}_4\text{O}_7 \cdot 10\text{H}_2\text{O}$, or a mixture of both is introduced into the kiln at the finishing temperature. The salt evaporates and reacts with the hot ware to form the glaze. This type of glaze has been applied to sewer pipe and some fine stoneware.

The most important factor in compounding a glaze, after a suitable maturing temperature has been obtained, is the matching of the coefficient of thermal expansion of the glaze and the body on which it is applied. A slightly lower coefficient for the glaze will place it in compression (the desired condition) when the ware cools.

The reverse state (with the glaze in tension because it has a higher coefficient) leads to the formation of fine hairline cracks, a condition known as crazing.

Glaze Materials

As reaction times, melting points, temperatures, and substrates have changed in the whiteware industry, the materials used in glaze formulation have also changed over time.

Silica is a major glaze component and is added in many forms, such as quartz, feldspar, or wollastonite. Silica acts as a glass former and is used to control thermal expansion and help impart acid resistance to the glaze.

Clay, such as kaolin, ball clay, china clay, or bentonite, continues to be the primary suspending agent used in ceramic glazes. The rheology characteristics required by the application method, as well as physical properties such as glaze drying time or shrinkage characteristics, need to be taken into account when selecting the clay to be used in a ceramic glaze. For example, glazing wet column brick requires glazes with up to 25% clay, while only 5%–10% clay is needed for glaze suspension.

Feldspathic minerals, such as soda and potash feldspar and nepheline syenite, remain some of the most commonly used raw materials. These materials are a major source of silica and alkali fluxes in a glaze. Feldspar can be used as either a flux or a refractory material in a glaze, depending on the firing temperature.

Alumina is normally added as calcined alumina or alumina trihydrate, although both clay and feldspars are also sources of alumina in the glaze. The alumina is used to improve the scratch resistance or abrasion resistance of the glaze and also influences the gloss level.

Alkaline earth oxide materials, such as calcium carbonate, wollastonite, and zinc oxide, are also generally added as raw materials. Other alkaline earth oxides, such as lead oxide, strontium oxide, barium oxide, and magnesium oxide, are more typically added in a fritted form. The alkaline earth oxides are beneficial because they provide fluxing action without having a major effect on glaze thermal expansion.

Zirconium silicate is the major opacifier used in ceramic glazes. However, tin oxide is used by some manufacturers, particularly if chrome–tin pigments are being used in the glaze. Using zircon-opacified frits to provide some or all of the zirconium silicate needed in a glaze is also becoming more common. This is especially true in fast-firing cycles, where the use of a high percentage of a refractory material (such as zirconium silicate) is not desirable.

Ceramic frits play a major part in glaze formulation. Frits continue to be a source of highly soluble oxides, such as soda, potassium, or boron. As firing cycles have grown shorter, however, material such as zircon, calcium, alumina, or barium are commonly added in the fritted form. In addition, frit producers are able to tailor frits formulations for particular uses and processes.

Glide

(1) Same as *slip*. (2) A noncrystallographic shearing movement, such as of one grain over another. (3) Referring to deformation within a grain, the term usually means plastic deformation by slip along the main planes, usually of closest packing. See *dislocation*.

Globular Cementite

Cementation in discrete globules rather than combined and pearlite. See *steel*.

G

Globular Transfer

In consumable electrode arc welding, a type of metal transfer in which molten filler metal passes across the arc as large droplets. Compare with *spray transfer* and *short-circuiting transfer*. See the term *short-circuiting transfer*.

Glow Discharge Spectroscopy

A surface analysis technique in which a glow discharge lamp provides a low-pressure argon environment for the specimen that forms the cathode of the high-voltage (800–1200 V) circuit. The plasma, or glow discharge, of Ar^+ ions bombards the specimen releasing material in a high energy state. The wavelength and intensity of the resultant radiation are measured to provide a quantitative analysis of the surface material.

Glucose

A syrupy liquid that is a monosaccharide, or simple sugar, occurring naturally in fruits and in animal blood or made by the hydrolysis of starch. It is also produced as a dry, white solid by evaporation of the syrup. Glucose is made readily from cornstarch by heating the starch with dilute hydrochloric acid, which is essentially the same process as occurs in the human body. Commercial glucose is made from cornstarch, potato starch, and other starches, but in Japan it is also produced from wood. Glucose is only 70% as sweet as sugarcane and has a slightly different flavor. It is used in confectionery and other foodstuffs for blending with sugarcane and syrups to prevent crystallization on cooling and it is usually cheaper than sugar. It is used in tobacco and inks to prevent drying and in tanning as a reducing agent. The name *glucose* is usually avoided by the manufacturers of edible products, because of prejudices against its substitution for sugar; but in reality it is a simple form of sugar easily digested. It is used in medicine as a blood nutrient and to strengthen heart action, and it may be harmful only in great excess. When free from starch, it is called *dextrose*. It is also marketed as corn syrup, but corn syrup is not usually pure glucose, as it contains some dextrine and maltose. The *maltose*, or *malt sugar*, or the combination has the empirical formula $\text{C}_{12}\text{H}_{22}\text{O}_{11}$. When hydrolyzed in digestion, it breaks down easily to glucose. It is produced from starch by enzyme action. When purified, it is transparent and free of malt flavor. It is not as sweet as the sucrose of sugarcane, but is used in confectionery and as an extender of sugarcane. *Dry corn syrup* is in colorless glasslike flakes. It is made by instantaneous drying and quick cooling of the syrup. Sweetose is a crystal-clear enzyme-converted corn syrup used in confectionery to enhance flavor and increase brightness.

Glucose derived from grapes is called *grape sugar*. The glucose in fruits is called *fruit sugar*, *levulose*, or *fructose*. This is dextroglucose, and when separated out, it is in colorless needles that melt at 219°F (104°C). It is used for intravenous feeding and is absorbed faster than glucose. It is also used in low-calorie foods and in honey to prevent crystallization. It is normally expensive but is made synthetically. It can be made from corn and is superior to corn syrup as a sweetening agent. *Maple syrup* is prepared by concentrating sap from the maple tree. *Molasses* is a by-product of sugarcane manufacture. *Corn sugar* is also a solid white powder, consisting of glucose with one molecule of water crystallization. When the refined liquor is cooled, the corn sugar crystallizes in a mother liquor known as *hydrol* or *corn-sugar molasses*. Ethyl glucoside is marketed as a colorless syrup

in water solution with 80% solids and a specific gravity of 1.272. It is noncrystallizing and is used as a humectant and plasticizer in adhesives and sizes.

Glue

Originally, a hard gelatin obtained from hides, tendons, cartilage, bones, skins, and heads of fish and of other animals and also an adhesive prepared from this substance by heating with water. Through general use, the term is now synonymous with the terms bond and adhesive. See also *adhesive*, *gum*, *mucilage*, *paste*, *resin*, and *sizing*.

The term *animal glue* is limited to *hide glue*, *extracted bone glue*, and *green bone glue*. Fish glue is not usually classified with animal glue nor is casein glue. The vegetable glues are also misnamed, being classified with the mucilages. Synthetic resin glues are more properly classified with adhesive cements. Animal glues are *hot-work glues* that are applied hot and bind on cooling. Good grades of glue are semitransparent, free from spots and cloudiness, and not brittle at ordinary temperature. *Bone glue* is usually light amber; the strong hide and sinew glues are light brown. The stiffening quality of glue depends upon the evaporation of water, and it will not bind in cold weather. Glues made from blood, known as *albumin glues*, and from casein are used for some plywood; however, they do not have the strength of the best grades of animal glue and are not resistant to mold or fungi. *Marine glue* is a glue insoluble in water, made from solutions of rubber or resins, or both. The strong and water-resistant plywoods are now made with synthetic resin adhesives.

Animal glue has been made since ancient times and is now employed for cementing wood, paper, and paperboard. It will not withstand dampness, but white lead or other material may sometimes be added to make it partly waterproof. Casein glues and other protein glues are more water resistant. *Soybean glue* is made from soybean cake and is used for plywood. It is marketed as dry. It has greater adhesive power than other vegetable glues, or pastes, and is more water resistant than other vegetable pastes. Hide glue is used in the manufacture of furniture, abrasive papers and cloth, gummed paper and tape, matches, and print rollers. The bone glues are used either alone or blended in the manufacture of cartons and paper boxes. Green bond glue is used chiefly for gummed paper and tape for cartons. In making bone glue, the bones are crushed, the greases are extracted by solvents, and the mineral salts are removed by dilute hydrochloric acid. The bones are then cooked to extract the glue. Glues are graded according to the quality of the raw material, method of extraction, and blend.

There are 16 grades of hide glue and 15 grades of bone glue. Those with high viscosity are usually the best. Most glue is sold in ground form but also as flake or pearl. Glues for such uses as holding abrasive grains to paper must have flexibility as well as strength, obtained by adding glycerin. The *animal protein colloid* of Swift & Co. is a highly purified bone glue is specially adapted for use as an emulsifier and for sizing, water paints, stiffening, and adhesives. Hoof and horn pith glue is the same as bone glue and is inferior to hide glue. *Fish glue* is made from the jelly separated from fish oil or from solutions of the skins. The best fish glue is made from Russian isinglass. Fish glues do not form gelatin well and are usually made into liquid glues for photographic mounting, gummed paper, household use, and use in paints and sizes. Liquid glues are also made by treating other glues with a weak acid. Pungent odors indicate defective glue. Glues made from decomposed materials are weak. Preservative such as sulfur dioxide or chlorinated phenol may be used. The melting point is usually about 140°F (60°C).

Glut

Metal bar or section providing filler material in forge welding. The glut becomes fully incorporated as a load-bearing member rather than merely occupying space.

Glue-Laminated Wood

An assembly made by bonding layers of veneer or lumber with an adhesive so that the grain of all laminations is essentially parallel.

Glue Line

Synonym for *bond line*.

Glue Line Thickness

Thickness of layer of cured adhesive.

Glycerin

A colorless, syrupy liquid with a sweet, burning taste, soluble in water and in ethyl alcohol. It is the simplest *trihydroxy alcohol*, with composition $C_3H_5(OH)_3$. It has a specific gravity 1.26, a boiling point of 554°F (290°C), and a freezing point of 68°F (20°C). It is also called *glycerol* and was used as a lotion under the name of *sweet oil* for more than a century after its discovery in 1783.

Glycerin occurs as *glycerides*, or combinations of glycerin with fatty acids, and vegetables and animal oils and fats and is a by-product in the manufacture of soaps and in the fractionation of fats, and is also made synthetically from propylene. Coconut oil yields about 14% glycerin, 11% palm oil, 10% tallow, 10% soybean oil, and 9% fish oils. It does not evaporate easily and has a strong affinity for water, and it is used as a moistening agent in products that must be kept from drying, such as tobacco, cosmetics, foodstuffs, and inks. As it is nontoxic, it is used as a solvent in pharmaceuticals, as an antiseptic in surgical dressings, as an emollient in throat medicines, and in cosmetics. Since a different type of group can replace anyone of or all three *hydroxyl groups* (OH), a large number of derivatives can be formed, and it is thus a valuable intermediate chemical, especially in the making of plastics. Commercially, the most important are the *alkyd resins*. It is also used as a plasticizer in resins and to control flexibility in adhesives and coatings. An important use is in nitroglycerin and dynamite.

Gob

(1) A portion of hot glass delivered by a feeder. (2) A portion of hot glass gathered on a punty or pipe.

Gob Process

A process whereby glasses delivered to a forming unit in *gob* form.

Gold and Gold Alloys

Gold (Au) is a soft, ductile, yellow metal, known since ancient times as a precious metal on which all material trade values are based. Commercially pure gold is 99.97% pure, and higher purity material is available.

The outstanding useful property of gold is its oxidation resistance. It is not attacked by the common acids when used singly.

It does, however, dissolve an aqua regia (nitric acid plus hydrochloric acid) and cyanide solutions and is attacked by chlorine above 80°C. It is resistant to dry fluorine up to about 300°C, hydrogen fluoride, dry hydrogen chloride, and dry iodine. It is also resistant to sulfuric acid, sulfur, and sulfur dioxide.

Gold is found widely distributed in all parts of the world. It is used chiefly for coinage, ornaments, jewelry, and gilding.

Gold is the most malleable of metals and can be beaten into extremely thin sheets. In most cases, gold is alloyed to increase its hardness without appreciable loss of oxidation resistance. Copper is a common alloying element along with silver and small amounts of the platinum metals. Some of these alloys can be heat treated to relatively high strengths. Gold and its alloys are worked into all the usual forms of sheet, wire, ribbon, and tubing.

A gram of gold can be worked into leaf covering 0.6 m², and only 0.0000084 cm thick, or into a wire 2.5 km in length. Precision casting is also used to form gold alloys, particularly for jewelry. The expense of gold and its low hardness are often offset by using it as a laminate or plating on base metals. It can also be applied to metals, ceramics, and some plastics by the thermal decomposition of certain gold compounds.

Cast gold has a tensile strength of 137 MPa. The specific gravity is 19.32 and the melting point 1063°C. It is not attacked by nitric, hydrochloric, or sulfuric acid, but is dissolved by aqua regia, or by a solution of azoimide, and is attacked by sodium and potassium cyanide plus oxygen. The metal does not corrode in air, only a transparent oxide film forming on the surface.

Gold alloys (Au–Ag–Cu and Au–Ni–Cu–Zn) can be made in a range of colors from white to many shades of yellow. For this reason, gold is widely used for jewelry and other decorative applications. Similar alloys (Au–Ag–Cu–Pt–Pd) are used in dentistry, the nobility of the alloys and their response to heat treatment hardening being of concern here. Gold–silver alloys have been used in low-current electrical contacts (under 0.5 A). Gold is often used in electrical and other equipment, which is used for standards and where stability is of prime concern.

Gold–gallium and gold–antimony alloys for electronic uses come in wire as fine as 0.013 cm in diameter and in sheet as thin as 0.003 cm. The maximum content of antimony in workable gold alloys is 0.7%. A gold–gallium alloy with 2.5% gallium has a resistivity of $15 \times 10^{-8} \Omega \text{ m}$ and has a tensile strength of 379 MPa and 22% elongation. Gold powder and gold sheet, for soldering semiconductors, are 99.999% pure. The gold wets silicon easily at a temperature of 371°C.

The corrosion resistance and melting point of gold also make it useful as a brazing material. It is used as well in chemical equipment, where its susceptibility to chlorine attack is not a problem. In particular, it is used to line reaction vessels and as a gasketing material.

Gold may be readily applied by electroplating from cyanide and other solutions. It may also be applied to some metals by simple immersion in special plating solutions. Plating has, of course, many decorative applications.

Gold plating is also used to make reflectors, particularly for the infrared wavelengths. Electrical components are often gold plated, especially for high frequencies, because of the low electrical resistance of gold. Vacuum tube grids may be gold plated to reduce electron emission and some electrical contacts are gold plated.

Gold may also be applied by using *liquid bright golds*. These are varnishlike solutions of gold compounds that may be applied at any suitable manner—brushing, spraying, printing, etc.—to metals, ceramics, and some plastics. After being applied, the material is heated to decompose the compound, depositing a tightly adhering

G

gold layer. Some gold alloys may also be applied in this matter. This method is used for the decoration of china and glassware, as well as for printed circuits and electrical resistance elements.

Gold is one of the noble metals, and it is one of the only two colored metals (copper being the other). It is soft and, being the most malleable of all metals, can be beaten into ultrathin gold leaf. The purity of gold is measured as a percentage or, for jewelry, coinage, and similar applications, in carats (parts per 24) or fineness (parts per 1000). Apart from decorative and coinage uses and its external *hoarding* value, it has considerable industrial application where its corrosion resistance justifies its cost.

Gold Bronze

An alloy of copper with about 4% aluminum (no gold) having a gold color.

Gold Filled

Covered on one or more surfaces with a layer of gold alloy to form a clad or composite material. Gold-filled dental restorations are an example of such materials.

Gold Leaf

Thin sheet gold of high purity typically 0.075–0.125 μm , 3–5 μin . thick.

Goldschmidt Process

The thermite reaction when used for extraction of metal from its ore.

Goniometer

(1) In *x-ray spectrometry*, an instrument devised for measuring the angle through which a specimen is rotated or for orienting a sample (e.g., a single crystal) in a specific way. (2) An instrument for measuring the orientation of the surfaces and planes of crystalline materials.

Goodman Diagram

See *fatigue*.

Gooseneck

In die casting, a spout connecting a molten metal holding pot, or chamber, with a nozzle or sprue hole in the die and containing a passage through which molten metal is forced on its way to the die. It is the metal injection mechanism in a *hot chamber machine*.

Gouging

In welding practice, the forming of a bevel or groove by material removal. See also *back gouging*, *arc gouging*, and *oxygen gouging*. A severe form of localized wear in which material is removed in a single pass or cut leaving a deep groove. Flame gouging is the use of some oxyfuel gas flame to melt defects or other unwanted features on a component surface. The molten material is vigorously ejected by the main gas stream or an additional stream leaving a deep groove. Thermal gouging is similar but includes processes in which heating is by an electric arc.

Gouging Abrasion

A form of high-stress abrasion in which easily observable grooves or gouges are created on the surface. See also *abrasion* and *low-stress abrasion*.

G-P Zone

A *Guinier–Preston zone*.

Graded Coating

A thermal sprayed deposit composed of mixed materials in successive layers that progressively change in composition from the constituent material of the substrate to the surface of the sprayed deposit.

Grade

In powder metallurgy, a specific, nominal chemical analysis powder identified by a code number, for example, cemented carbide manufacturers grade 74 M 60 FWC (74 is usage; M is equipment manufacturer; 60 is nominal HRC; FWC is fine cut tungsten carbide).

Graded Abrasive

An abrasive powder in which the sizes of the individual particles are confined to certain specified limits. See also *grit size*.

Graded Coating

A thermal spray coating consisting of several successive layers of different materials, for example, starting with 100% metal, followed by one or more layers of metal–ceramic mixtures, and finishing with 100% ceramic.

Gradient Coating

See *graded coating*.

Gradient Elution

A technique for improving the efficiency of separations achieved by *liquid chromatography*. It refers to a stepwise or continuous change with time in the mobile phase composition.

Graft Copolymers

A chain of one type of polymer to which side chains of a different type are attached or grafted.

Grain

(1) A portion of a metal or alloy having all of its atoms in alignment forming a crystal structure. Grain is largely synonymous with crystal. Metals are comprised of grains, much as a lump of sugar is, except that metals have no gaps at the interfaces and bonding between grains is strong. The interface between grains is termed the grain boundary that may be visualized as a band of material in which the atoms have a virtually random arrangement as they blend from the lattice of one grain to that of the neighboring grain. In most cases, the grain boundaries are not a weak zone. The exceptions

include high temperatures, see *creep*, in certain cases of *embrittlement*. (2) A unit of weight, the smallest on the apothecaries' scale, 1 grain = 0.00208 oz troy = 0.00229 oz av. = 64.7989 mg. (3) The elongated fibrous cell structure of wood. (4) An individual crystal in a polycrystalline material; it may or may not contain twinned regions and subgrains.

Grain Boundary

A narrow zone in a metal or ceramic corresponding to the transition from one crystallographic orientation to another, the separating one *grain* from another; the atoms in each grain are arranged in an orderly pattern.

Grain-Boundary Corrosion

Same as *intergranular corrosion*. See also *interdendritic corrosion*.

Grain-Boundary Diffusion

One of the diffusion mechanisms in *sintering*. It is characterized by a very high diffusion rate because of an abundance of imperfections in the grain boundaries. See also *surface diffusion* and *volume diffusion*.

Grain-Boundary Etching

In metallography, the development of intersections of grain faces with a polished surface. Because of severe, localized crystal deformation, grain boundaries have higher dissolution potential than grains themselves. Accumulation of impurities in grain boundaries increases this effect.

Grain-Boundary Liquation

An advanced stage of overheating of metals in which material in the region of austenitic grain boundaries melts. Also termed *burning*.

Grain-Boundary Sulfide Precipitation

An intermediate state of overheating of metals in which sulfide inclusions are redistributed to the austenitic grain boundaries by partial solution at the overheating temperature and reprecipitation during subsequent cooling.

Grain Coarsening

A heat treatment that produces excessively large austenitic grains in metals.

Grain Contrast

Variations in appearance of the grains on a prepared surface. The variation may be produced by various techniques including etching or heat tinting, and examination may be by normal light or polarized light.

Grain-Contrast Etching

In metallography, the development of grain surfaces lying in the polished surface of the microsection. These become visible through

differences in reflectivity caused by reaction products on the surface or by differences in roughness.

Grain Fineness Number

A system developed by the American Foundry Society for rapidly expressing the average grain size of a given sand. It approximates the number of meshes per inch of that sieve that would just pass the sample.

Grain Flow

Fiberlike lines on polished and etched sections of forgings caused by orientation of the constituents of the metal in the direction of working during forging. Grain flow produced by proper die design can improve required *mechanical properties* of forgings. See also *flow lines* and *forged structure*.

Grain Growth

(1) An increase in the average size of the grains in polycrystalline material, usually as a result of heating at elevated temperature. (2) In polycrystalline materials, a phenomenon occurring fairly close below the melting point in which the larger grains grow still larger, while the smallest ones gradually diminish and disappear. See also *recrystallization*.

Graining

The process of vigorously stirring or agitating a partially solidified material to develop large grains having a thin oxide coating.

Grain Refinement (Metals)

The manipulation of the solidification process to cause more (and therefore smaller) grains to be formed and/or to cause the grains to form specific shapes. The term refinement is usually used to denote a chemical addition to the metal but can refer to control of the cooling rate.

Grain Refiner

A material added to a molten metal to induce a finer-than-normal grain size in the final structure.

Grain Size

(1) For metals, a measure of the areas or volumes of grains in a polycrystalline material, usually expressed as an average when the individual sizes are fairly uniform. In metals containing two or more phases, grain size refers to that of the matrix unless otherwise specified. Grain size is reported in terms of number of grains per unit area or volume, in terms of average diameter, or as a grain size number derived from area measurements. (2) For grinding wheels, see the preferred term *grit size*.

Grain Size Analysis

The measurement of grain size in metals or the measurement of the particle size of powders.

G

Grain Size Distribution

Measures of the characteristic grain or crystalline dimensions (usually, diameters) in a polycrystalline solid or of their populations by size increments from minimum to maximum. This is usually determined by microscopy.

Gram-Equivalent Weight

The mass in grams of a reactant that contains or reacts with Avogadro's number of hydrogen atoms. See also *Avogadro's number*.

Gram-Molecular Weight

The mass of a compound in grams equal to its molecular weight.

Granite

A coarse-grained, igneous rock having an even texture and consisting largely of quartz and feldspar with often small amounts of mica and other minerals. There are many varieties. Granite is very hard and compact, and it takes a fine polish, showing the beauty of the crystals. It is the most important building stone and is also used as an ornamental stone. An important use is for large rolls in pulp and paper mills. Granite surface plates, for machine-shop layout work, are made in sizes up to 30 × 72 in. (76 × 183 cm) and 10 in. (25 cm) thick, ground and highly polished to close accuracy. It is extremely durable, and since it does not absorb moisture, as limestone and sandstone do, it does not weather or crack as the stones do. The colors are usually reddish, greenish, or gray. The hard composite igneous rock *diabase*, called "black granite," is used for making precision parallels for machine-shop work.

Granular

(1) With reference to volume comprising separate, approximately equiaxed grains. (2) With reference to surfaces having a rough irregular texture, rather like coarse-grained lump sugar.

Granular Fracture

A type of irregular surface produced when metal is broken that is characterized by a rough, grainlike appearance, rather than a smooth or fibrous one. It can be subclassified as *transgranular fracture* or *intergranular fracture*. This type of fracture is frequently called *crystalline fracture*; however, the interference that the metal broke because it *crystallized* is not justified, because all metals are crystalline in the solid state. See also *fibrous fracture* and *silky fracture*.

Granular Powder

A powder having equidimensional but nonspherical particles.

Granular Structure

Nonuniform appearance of finished plastic material due to retention of, or incomplete fusion of, particles of composition, either within the mass or on the surface.

Granulated Metal

Small pellets produced by pouring liquid metal through a screen or by dropping it onto a revolving disk and, in both instances, by chilling with water.

Granulation

Any process for producing metals as granules including pouring through a mesh or onto a spinning disk.

Graphite

Graphite is a form of carbon. It was formerly known as black lead, and when first used for pencils, it was called Flanders' stone. It is a natural variety of elemental carbon with a grayish, black color in a metallic tinge.

Carbon and graphite have been used in industry for many years, primarily as electrodes, arc carbons, brush carbons, and bearings. In the last decade or so, the development of new types and emergence of graphite fibers as a promising reinforcement for high-performance composites have significantly increased the versatility of this family of materials.

Types of Graphite

Recrystallized graphite is produced by a proprietary hot-working process that yields recrystallized or *densified* graphite with specific gravities in the 1.85–2.15 range, as compared with 1.4–1.7 for conventional graphites. The major attributes of the material are a high degree of quality reproducibility, improved resistance to creep, and grain orientation that can be controlled from highly anisotropic to relatively isotropic, lower permeability than usual, absence of structural macroflaw, and ability to take a fine surface finish.

Graphite fibers are produced from organic fibers. One line of development used rayon as the precursor, and the other used polyacrylonitrile (PAN). Although the detailed processing conditions for converting cellulose or PAN into carbon and graphite fibers differ in detail, they both consisted fundamentally of a sequence of thermal treatments to convert the precursor into carbon by breaking the organic compound to leave a *carbon polymer*. The fibrous carbon formed by the controlled pyrolysis of organic precursor fiber was viscous rayon or acrylonitrile. Carbon fibers produced by the rayon-precursor method have a fine-grained, relatively disordered microstructure, which remains even after treatment at temperatures up to 3000°C. Graphite crystallites with a long-range 3D order do not develop. In both the rayon and PAN processes, a high degree of preferred crystal orientation was responsible for the high elastic modulus and tensile strength.

Although the names *carbon* and *graphite* are used interchangeably when related to fibers, there is a difference. Typically, PAN-based carbon fibers are 93%–95% carbon by elemental analysis, whereas graphite fibers are usually 99+%. The basic difference is the temperature at which the fibers are made or heat treated. PAN-based carbon is produced at about 1316°C, whereas higher-modulus graphite fibers are graphitized at 1899°C–3010°C. This also applies to carbon and graphite cloths. Unfortunately, with only rare exceptions, none of the carbon fibers is ever converted into classic graphite regardless of the heat treatment.

When used in composites, the fibers are generally made into yarn containing some 10,000 fibers. Depending on the precursor fiber, their tensile strength ranges from 1378 to nearly 3445 MPa, and their modulus of elasticity is from 0.2 million to 0.5 million MPa.

Graphite fiber-reinforced graphite composites can be used at temperatures in excess of 3500°C. No compatibility problems exist because the graphite fiber or filament is in a graphite matrix. This composite system is good in reducing environments; in air or oxidizing atmospheres, special protective coatings are sometimes needed.

The graphite matrix is produced by the pyrolytic decomposition of polymeric systems in which the graphite fiber or filaments are originally embedded. Although many of the matrix starting materials are considered proprietary, usable polymer systems include phenolic, furfuryl ester, and epoxy resins. Graphite-graphite composites, even those fabricated with low-modulus materials, are up to 20 times stronger than conventional carbon and graphite materials. At a density of approximately 1384 kg/m³, they also are about 30% lighter than conventional carbons. They provide a very high strength-to-weight ratio at temperatures to 3300°C and exhibit superior thermal stability. Most Gr-Gr composites are more than 99% carbon (carbon content about 99.5%–99.9%). This high purity provides a good chemical inertness and corrosion resistance. Gr-Gr composites are not wetted by molten metals, which makes them ideally suited to metallurgical applications where high strength, lightweight, erosion resistance, and good thermal conductivity are important. Typical properties are tensile strength, 56.5 MPa; flexural strength, 76 MPa; compressive strength, 276 MPa; and modulus, 17.2 GPa.

Graphite fiber-epoxy composites provide exceptionally high strength and stiffness, and because of their lightweight are finding an increasing use of these composites for golf club shafts, tennis racket frames, and a multitude of sports equipment, as well as extensive use in the aerospace industry (wings, engine casings, fittings etc.), is found.

PT graphites are graphite fibers impregnated or bonded with an organic resin (such as furfural) and then carbonized. The result is a graphite-reinforced carbonaceous material with a high degree of thermal stability. The composite has a low density (0.93–1.2 specific gravity) and what is reported to be the highest strength-to-weight ratio of the material at temperatures in the 2204°C–2706°C range.

Colloidal graphite consists of natural or artificial graphite in very fine particle form, coated with a protective colloid and dispersed in a liquid. The selection of the liquid—water, oils, or synthetics—is made on the basis of intended use of the product. Significant characteristics of colloidal graphite dispersions are that the graphite particles remain in suspension indefinitely and the particles *wick*—that is, they are carded by the liquid to most places penetrated by the liquid.

The supergraphite used for rocket casings and other heat-resistant parts is recrystallized molded graphite. It will withstand temperatures to 3038°C. Pyrolytic graphite is an oriented graphite. It has high density, with a specific gravity of 2.22; has exceptionally high heat conductivity along the surface, making it very flame resistant; is impermeable to gases; and will withstand temperatures to 3704°C. It is made by deposition of carbon from a stream of methane on heated graphite and the growing crystals formed with thin planes parallel to the existing surface. The structure consists of close-packed columns of graphite crystals joined to each other by strong bonds along the flat planes, but with weak bonds between layers. This weak and strong electron bonding provides a laminal structure. The material conducts heat and electricity many times faster along the surface than through the material. The flexural stresses 172 MPa compared with less than 55 MPa for the best conventional graphite. At 2760°C the tensile strength is 275 MPa. Sheets as thin as 0.003 cm are impervious to liquids or gases. It is used for nozzle inserts and reentry parts for spacecraft, as well as for atomic shielding with an addition of boron.

Mechanical Properties

The degree of anisotropy in graphites varies, but cross grain strengths are usually substantially lower. Tensile strengths of the newer engineering graphites are substantially higher, with that of pyrolytic graphite reaching around 95.2 MPa. See *carbon* and *carbon composites*.

Graphitic Carbon

Carbon- and iron-base materials that are in the free form as graphite rather than combined with iron or another element.

Graphitic Corrosion

A form of corrosion affecting graphitic cast irons in aggressive aqueous environments, particularly soils containing sulfate-reducing bacteria. An electrolytic cell is formed in which the iron matrix is progressively corroded, leaving a weak mass of graphite and iron oxide. The corrosion product is the same volume as the original material and does not readily detach so even extensive deep graphitic corrosion may not be obvious to a visual examination. It occurs in relatively mild aqueous solutions and on buried pipe and fittings.

Graphitic Steel

Alloy steel made so that part of the carbon is present as graphite.

Graphitization

The formation of free carbon, that is, graphite in iron and steel. When it occurs during solidification, it is termed primary graphitization. When it occurs in the solid state, it is termed secondary graphitization. The process may be deliberately induced in the production of cast irons. In steels, graphitization may occur as a result of very prolonged exposure to high temperatures, for example, about 100,000 h in the temperature range 850°C–900°C for mild steel, perhaps 50°C higher for 0.5% molybdenum steel. Aluminum deoxidized steel is relatively more susceptible and imposed stress accelerates the rate of graphitization. The term has also been used, perhaps not very accurately, with reference to graphitic corrosion.

Graphitization (Organic Materials)

The process of pyrolyzation in an inert atmosphere at temperatures in excess of 1925°C (3500°F), usually as high as 2480°C (4500°F), and sometimes as high as 5400°C (9750°F), converting carbon to its crystalline allotropic form. Temperature depends on precursor and properties desired.

Graphitizing

Annealing a ferrous alloy such that some or all of the carbon precipitates as graphite.

Graticule

A grating, network, or scale on a lens or disk inserted in the microscope. Its image is superimposed on the material being examined allowing features of interest to be measured or their positions plotted.

G

Gravel

A natural material composed of small, usually smooth, rounded stones or *pebbles*. It is distinguished from sand by the size of the grain, which is usually above 0.25 in. (0.64 cm); but gravel may contain large stones up to 3 in. (7.62 cm) in diameter and some sand. It will also contain pieces of shale, sandstone, and other rock materials. Gravel is used in making concrete for construction and as a loose paving material. Commercial gravel is washed to remove the clay and organic material and is screened. *Pea gravel* is screened gravel used for surfacing with asphalt or for roofing. Gravel is sold in cubic yards (cubic meters) or in tons (metric tons) and shipped by weight.

Gravity Die Casting

See *permanent mold*.

Gravity Hammer

A class of forging hammer in which energy for forging is obtained by the mass and velocity of a freely falling ram and the attached upper die. Examples are the *board hammer* and *air-list hammer*.

Gravity Segregation

The variable composition of a casting or ingot caused by settling out of heavy constituents, or rising of light constituents, before or during solidification.

Gravity Welding

Processes in which a metal arc electrode is carried by a device that locates the electrode tip at the start of the joint and, once the arc has been struck, directs the falling electrode along the line of the joint without further assistance from the operative. The device is usually very simple, for example, no more than a bipod set across the joint.

Gray Body

A body having the same spectral emittance at all wavelengths.

Gray Cast Iron

See *gray iron*.

Gray Iron

A broad class of ferrous casting alloys (*cast irons*) normally characterized by a microstructure of flake graphite in a ferrous matrix. Gray irons usually contain 2.5%–4% C, 1%–3% Si, and additions of manganese, depending on the desired microstructure (as low as 0.1% Mn in ferritic gray irons and as high as 1.2% in pearlitics). Sulfur and phosphorus are also present in small amounts as residual impurities. See the term *flake graphite*.

Gray Irons

Gray iron is characterized by the presence of flakes of graphite supported in a matrix of ferrite, pearlite, austenite, or any other matrix

attainable in steel. The major dimensions of the flakes may vary from about 0.05 to 1.0 mm. Because of their low density, the graphite flakes occupy about 10% of the metal volume. The flakes interrupt the continuity of the matrix and have a large effect on the properties of gray iron. In addition, the flakes give a fractured surface that is great. This is responsible for the name “gray iron.”

High carbon content and the flakes of graphite give gray iron unique properties as follows:

1. Lowest melting point of the ferrous alloys, so that low-cost refractories can be used for molds
2. High fluidity in the molten state, so that complex and thin designs can be cast
3. Excellent machinability, better than steel
4. High damping capacity and ability to absorb vibrations
5. High resistance to wear involving sliding
6. Low ductility and low impact strength when compared with steel

Gray iron is by far the most common and widely used cast iron.

Gray iron is encountered almost exclusively as shaped castings used either with or without machining. Typical applications include

1. Pipe for underground service for water or gas
2. Ingot molds into which steel and other metals are cast
3. Cylinder blocks and heads for internal combustion engines
4. Frames and end bells for electric motors
5. Bases, frames, and supports for machine tools
6. Sanitaryware such as sinks and bathtubs (usually coated with porcelain enamel)
7. Pumps, car wheels, and transmission cases

The major industries that consume gray iron castings are as follows: automotive, building and construction, utilities, machine tools, architectural, rolling mills (steel plants), general machinery, household appliances, and heating equipment.

For engineering applications where tensile strength is important, gray iron usually is classified on the basis of minimum tensile strength in a specimen machine from a separately cast test bar.

Mechanical and Physical Properties

Compressive strength: Unusually high; at least three times the tensile strength.

Modulus of elasticity: Increases with tensile strength; about 0.87×10^5 MPa for a tensile strength of 136 MPa and up to about 1.45×10^5 MPa for a tensile strength of 480 MPa.

Endurance limit: About 35%–50% of tensile strength. Gray iron is relatively insensitive to the effect of notches.

Damping capacity: Very high, especially in irons of high carbon content. Specific damping capacity is about 10 times that of steel.

Specific gravity: Varies from about 6.8 for high-carbon, low-strength irons to about 7.6 for low-carbon, high-strength irons.

Coefficient of thermal expansion: Slightly lower than that of steel.

Coefficient of thermal conductivity: About the same as many other ferrous alloys; about 0.11–0.14 in CGS units. It can be lowered appreciably by adding alloying elements.

Grease

A lubricant composed of an oil thickened with a soap or other thickener to a semisolid or solid consistency. A lime-base grease is prepared from lubricating oil and calcium soap. Sodium-, barium-, lithium-, and aluminum-base greases are also used. Greases may contain various additives. The liquid phase may also be a synthetic fluid.

Green

This term is often used to indicate a product and a preliminary state of preparation, for example, green compact—the pressed powder compact prior to sintering—or green strength, the strength of such a compact. See unsintered (not sintered).

Green Ceramic

An unsintered ceramic.

Green Compact

An unsintered powder-metallurgy or ceramic compact.

Green Liquor

The liquor resulting from dissolving molten smelt from the kraft recovery furnace in water. See also *kraft process* and *smelt*.

Green Rot

A form of high-temperature attack on stainless steels, nickel–chromium alloys, and nickel–chromium–iron alloys subjected to simultaneous oxidation and carburization. Basically, attack occurs first by precipitation of chromium as chromium carbide and then by oxidation of the carbide particles.

Green Sand

A naturally bonded sand, or a compounded molding sand mixture, that has been *tempered* with water and that is used while still moist.

Green Sand Core

(1) A *core* made of *green sand* and used as rammed. (2) A sand core that is used in the unbaked condition.

Green Sand Mold

A casting mold composed of moist prepared molding sand. This is in contrast with *dry sand mold*.

Green Strength (Foundry Sands)

The strength of a tempered sand mixture at room temperature.

Green Strength (Plastics)

The mechanical strength of material that, while cure is not complete, allows removal from the mold and handling without tearing or permanent distortion.

Green Strength (Powder Compacts)

(1) The ability of a *green compact* to maintain its size and shape during handling and storage prior to *sintering*. (2) The tensile or compressive strength of a green compact.

Greenware

A term for formed ceramic articles in the unfired condition.

Greige, Gray Goods

Any fabric before finishing, as well as any yarn or fiber before bleaching or dyeing; therefore, fabric with no finish or size.

Grey (Cast) Iron

See *cast iron*.

Grey Tin

The allotrope of tin stable below -13°C that is hard and friable. In practice, it forms when tin is cooled below about -20°C and is inhibited by alloying additions of lead above 5% or antimony above 0.1%.

Griffith Critical Crack

The sharp tipped crack, assumed to be present in brittle materials and having, at its tip, a stress concentration sufficient to explain the difference between the high theoretical strength of the material and a much lower strength observed in practice.

Grignards

Reagents formed by the reaction of metallic magnesium and an organic halide—chloride, bromide, or iodide—in the presence of an ether solvent and the absence of water. Grignards are used to make products, including organometallics, pharmaceuticals, fungicides, and aromatic phosphenes. Potential applications include polymerization catalysts for methyl methacrylate, polyethylene, and polypropylene as well as biotechnology products.

Grindability

Relative ease of grinding, which is analogous to *machinability*.

Grindability Index

A measure of the grindability of a material under specified grinding conditions, expressed in terms of volume of material removed per unit volume of wheel wear.

Grinding

Removing material from a workpiece with a grinding wheel or abrasive belt.

1. *Surface grinding*: Producing a flat surface with a rotating grinding wheel as the workpiece passes under.
2. *Creep-feed grinding*: A subset of surface grinding, creep-feed grinding produces deeper (full) depths of cut at slow traverse rates.

G

3. *Cylindrical grinding*: Grinding the outside diameters of cylindrical pieces held between centers.
4. *Internal grinding*: Grinding the inside of a rotating workpiece by use of a wheel spindle that rotates and reciprocates through the length of depth of the hole being ground.
5. *Centerless grinding*: Grinding cylindrical surfaces without use of fixed centers to rotate the work. The work is supported and rotates between three fundamental machine components: a grinding wheel, the regulating wheel, and the work guide blade.
6. *Gear (form) grinding*: Removal of material to obtain correct gear tooth form by grinding. This is one of the more exact methods of finishing gears.
7. *Thread grinding*: Thread cutting by use of suitably formed grinding wheel.

Grinding Burn

Surface damage caused resulting from frictional heating during grinding and similar operations. Damage may include cracking, grain-boundary oxidation, local softening, local rehardening with brittle martensite (in the case of steel), and the introduction of residual stresses.

Grinding Cracks

Surface cracking resulting from severe grinding. The frictional heating causes local surface deformation that on cooling induces high levels of tensile residual stress. In addition, steel components may be locally hardened. These various consequences render the material liable to low ductility cracking on cooling. See also *grinding sensitivity*.

Grinding Fluid

An oil- or water-based fluid introduced into grinding operations to (1) reduce and transfer heat during grinding, (2) lubricate during chip formation, (3) wash loose chips or swarf from the grinding belt or wheel, and (4) chemically aid the grinding action or machine maintenance.

Grinding Oil

An oil-type grinding fluid; it may contain additives, but not water.

Grinding Pebbles

Hard and tough, rounded small stones, usually of flint, employed in cylindrical mills for grinding ores, minerals, and cement. Quantities of flint pebbles come from Denmark and Greenland for use in tube mills. They are smooth, round pebbles formed by the washing of the sea on the chalk cliffs, and they come from the islands off the Danish coast. Small pebbles, 0.5 in. (1.27 cm) in diameter, are used for polishing iron castings by tumbling.

The *tumbling abrasives*, for use in tumbling barrels, come in aluminum oxide or silicon carbide preformed balls, cubes, triangles, or cylinders of various sizes to conform to the parts being tumble polished.

Grinding Relief

A groove or recess located at the boundary of a surface to permit the corner of the wheel to overhang during grinding.

Grinding Sensitivity

Susceptibility of a material to surface damage such as *grinding cracks*; it can be affected by such factors as hardness, microstructure, hydrogen content, and residual stress.

Grinding Stress

Residual stress, generated by grinding, in the surface layer of work. It may be tensile or compressive, or both.

Grinding Wheel

A cutting tool of circular shape made of abrasive grains bonded together. See the term *diamond wheel*.

Grindstones

Sandstones employed for grinding purposes. Grindstones are generally used for the sharpening of edged tools and do not compete with the hard emery, aluminum oxide, and silicon carbide abrasive wheels that are run at high speeds for rapid cutting. Grindstones are quarried from the sandstone deposits and made into wheels usually ranging from 1 to about 6 ft (0.3 to about 1.8 m) in diameter and up to 16 in. (41 cm) in thickness. They are always operated at low speeds because of their inability to withstand high centrifugal stresses. The grades vary from coarse to fine. Good grindstones have sharp grains, without an excess of cementing material that will cause the stone to glaze in grinding. The texture must also be uniform so that the wheel will wear evenly. The hard silica grains are naturally cemented together by limonite, clay, calcite, quartz, or mixtures. Too much clay causes crumbling, while too much calcite results in disintegration in the atmosphere. An excess of silica results in a stone that is too hard.

Gripper Dies

The lateral or clamping dies used in a forging machine or mechanical upsetter.

Grit

Crushed ferrous or synthetic abrasive material in various mesh sizes that is used in abrasive blasting equipment to clean castings. For materials used for grinding belts or grinding wheels, the term *abrasive* is preferred. See also *blasting* or *blast cleaning*.

Grit Blasting

(1) *Abrasive blasting* with small irregular pieces of steel, malleable cast iron, or hard nonmetallic materials. (2) Processes in which grit is projected at a surface to remove scale, paint, etc. The metal or mineral grit may be entrained in a high velocity air stream or flung from a high-speed wheel (a Wheelabrator). If the grid is not trained in water, various terms such as Hydra blasting are used.

Grit Size

Nominal size of abrasive particles in a grinding wheel, corresponding to the number of openings per linear inch in a screen through which the particles can pass.

Grizzly

A set of parallel bars (or grating) use for coarse separation or screening of ores, rock, or other material.

Grog

A hard granular material added to a refractory to reduce shrinkage and improve resistance to thermal shock.

Grommet/Grummet

A link of material, for example, twisted rope rowlocks or a pad of material to prevent chafing such as the circumferentially slit range of rubber, inserted to sit astride the edge of a hole in sheet metal.

Groove (Thermal Spraying)

A method of surface roughening in which grooves are made and the original surface roughened and spread. This is also called rotary roughening.

Groove (Welding)

An opening or channel in the surface of a part or between two components that provides space to contain a weld.

Groove Angle

The total included angle of the groove between parts to be joined. Thus, this is the sum of two bevel angles, either or both of which may be 0°.

Groove Face

The portion of a surface or surfaces of a member included in a groove. See also the term *root of joint*.

Groove Radius

The radius used to form the shape of a J- or U-groove weld joint.

Groove Type

The geometric configuration of a groove.

Groove Weld

A weld made in the groove between two members. The standard types are square, single bevel, single flare bevel, single flare-V, single-J, single-U, single-V, double bevel, double flare bevel, double flare-V, double-J, double-U, and double-V. See the terms *double-bevel groove weld* and *single-bevel groove weld*.

Gross Energy Requirement

The total energy expended in producing a material or component from the ore mining stage to its installation in service.

Grossmann Number (H)

A ratio describing the ability of a quenching medium to extract heat from a hot steel workpiece in comparison to still water defined by the following equation:

$$H = \frac{h}{2k}$$

where

h is the heat-transfer coefficient

k is the conductivity of the metal

Gross Porosity

In weld metal or in a casting, pores, gas holes, or globular voids that are larger and in much greater numbers than those obtained and good practice.

Gross Sample

One or more increments of material taken from a larger quantity (lot) of material for assay or record purposes. This is also termed bulk sample or lot sample. See also *increment* and *lot*.

Groundbed

A buried item, such as junk steel or graphite rods, that serves as the *anode* for the *cathodic protection* of pipelines or other buried structures. See also *deep groundbed*.

Ground Connection

In arc welding, a device used for attaching the work lead (ground cable) to the work.

Ground-Support Cable

A cable construction, usually rugged and heavy, for use in control or power systems.

Group

The specimens tested at one time, or consecutively, at one stress level. A group may comprise one or more specimens.

Group (of Elements)

See *atomic structure*.

Growth (Cast Iron)

A permanent increase in the dimensions of cast iron resulting from repeated or prolonged heating at temperatures above 480°C (900°F) due to either graphitizing of carbides or oxidation. At such temperatures, the cementite breaks down forming ferrite plus graphite and oxygen permeates along the graphite causing internal oxidation. Both effects cause a volume increase that may lead to cracking.

G

Guard

(1) A device, often made of sheet metal or wire screening, that prevents accidental contact with moving parts of machinery. (2) In electroplating, it is the same as *robber*.

Guerin Process

A *rubber-pad forming* process for forming sheet metal. The principal tools are the rubber pad and form block, or punch.

Guide

The parts of a drop hammer or press that guide the up-and-down motion of the ram in a true vertical direction.

Guide Bearing

A bearing used for positioning a slide or for axial alignment of a long rotating shaft.

Guided Bend

The bend obtained by use of a plunger to force the specimen into a die in order to produce the desired contour of the outside and inside surfaces of the specimen.

Guided Bend Test

A test in which the specimen is bent to a definite shape by means of a punch (mandrel) and a bottom block.

Guide Mill

A small handbill with several stands in a train and with guides for the work at the entrance to the rolls.

Guide Pin Bushings

Bushings, pressed into a die shoe, that allow the *guide pins* to enter in order to maintain punch-to-die alignment.

Guide Pins

Hardened, ground round pins or posts that maintain alignment between punch and die doing the fabrication, setup, operation, and storage. If the press slide is out of alignment, the guide pins cannot make the necessary correction unless heel plates are engaged before the pins enter the bushings. See also *heel block*.

Guillet Diagram

A diagram predicting a steel microstructure on the basis of the alloy contents that are defined in terms of their equivalent effects relative to nickel and carbon.

Guillet Equivalent

Generally, the factor by which the percentage quantity of an element has to be multiplied to indicate its effect on some characteristic such as microstructure. This term is used particularly regarding

the structure of brass evaluated in terms of the equivalent percent of zinc. The Guillet equivalents for brass are 5× aluminum, 2× tin, 2× magnesium, 10× silicon, 1× lead, 0.9× iron, 0.5× manganese, and –1.2× nickel. The products of each element percentage times its factor are added to the actual zinc content to give the zinc equivalent.

Guinier–Preston (G–P) Zone

A small precipitation domain in a supersaturated metallic solid solution. A G-P zone has no well-defined crystalline structure of its own and contains an abnormally high concentration of solute atoms. The formation of G-P zones constitutes the first stage of precipitation and is usually accompanied by a change in properties of the solid solution in which they occur.

Gum (Adhesives)

Any of the class of colloidal substances exuded by or prepared from plants, sticky when moist, composed of complex carbohydrates and organic acids, which are soluble or swell in water. The term gum is sometimes used loosely to denote various materials that exhibit gummy characteristics under certain conditions, for example, gum balata, gum benzoin, and gum asphaltum. Gums are included by some of the category of natural resins. See also *adhesive*, *glue*, and *resin*.

Gum (Lubrication)

In lubrication, a rubberlike, sticky deposit, black or dark brown in color, that results from the oxidation and/or polymerization of fuels and lubricating oils. Harder deposits are described as *lacquers* or *varnishes*.

Gun

See the preferred terms *arc welding gun*, *electron beam gun*, *resistance welding gun*, *soldering gun*, and *thermal spraying gun*.

Gun Drill

A drill, usually with one or more flutes and with coolant passages through the drill body, used for deep hole drilling. See the term *drill*.

Gun Extension (Thermal Spraying)

An extension tube attached in front of a thermal spraying device to permit spraying within confined areas or deep recesses.

Gunmetal

The name for a *casting bronze*, C90500, containing 88% copper, 10% tin, and 2% zinc. It was originally used for small cannons but is now used where the golden color and strong, crystalline structure are desired. It casts and machines well and is suitable for making steam and hydraulic castings, valves, and gears. It has a tensile strength of 221–310 MPa, with elongation 15%–30%. This alloy is similar to *G bronze* (C90300), which contains 88% copper, 8% tin, and 4% zinc. *Gunmetal ingot* may have the zinc replaced by 2% lead. Such an alloy is easier to machine but has less strength. Modified gunmetal contains lead in addition to the zinc. It is used for gears

and bearings. A typical modified gunmetal contains 86% copper, 9.5% tin, 2.5% lead, and 2% zinc.

Gunpowder

Also known as *black powder*. An explosive extensively used for blasting purposes and for fireworks. It was introduced into Europe prior to 1250 and was the only propellant used in guns until 1870. It is now superseded for military uses by high explosives. Black powder deteriorates easily in air from the absorption of moisture. It is a mechanical mixture of potassium nitrate, charcoal, and sulfur, in the usual proportions of 75%, 15%, and 10%. More saltpeter increases the rate of burning; additional charcoal decreases the rate. A slow-burning powder for fireworks rockets may have only 54% saltpeter and 32% charcoal. Commercial black powder comes in grains of graded sizes and is glazed with graphite. The grain sizes are known as *pebble powder*, large grain or fine grain, *sporting powder*, *mining powder*, *Spanish spherical powder*, and *cocoa powder*. A temperature of about 3712°F (2100°C) is produced by the explosive. Gunpowder is the slowest acting of all the explosives, and it has a heaving, not a shattering, effect. Hence, it is effective for blasting and breaking up stone. Blasting powder is divided by DuPont into two grades: A and B. The *A powder* contains saltpeter; the *B powder* contains nitrate of soda. The saltpeter concentration varies from 64% to 74% in commercial formulations. The other ingredients are the usual sulfur and charcoal. The B powder is not so strong or water resistant as A powder but is cheaper and is extensively used. *Pellet powder* is blasting powder made up in cylindrical cartridges for easier use in mining. *White gunpowder* is a powder in which the saltpeter is replaced by potassium chlorate. It is very sensitive and explodes with violence. It is used only for percussion caps and fireworks.

Gusset

A reinforcement, usually a plate of triangular form set between two surfaces meeting at an angle.

Gutter

A depression around the periphery of a forging *die impression* outside the flash pan that allows space for the excess metal, surrounds the finishing impression, and provides room for the excess metal used to ensure a sound forging. It is a shallow impression outside the parting line.

Gypsum

Gypsum is the most common sulfate mineral, characterized by the chemical formula $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$; it shows little variation from this composition.

Gypsum is one of the several evaporite minerals. This mineral group includes chlorides, carbonates, borates, nitrates, and sulfates. These minerals precipitate in seas, lakes, caves, and salt flats due to concentration of ions by evaporation. When heated or subjected to solutions with very large salinities, chips and converts to bassanite ($\text{CaSO}_4 \cdot \text{H}_2\text{O}$) or anhydrite (CaSO_4). Under equilibrium conditions, this conversion to anhydrite is direct. The conversion occurs above 42°C in pure water.

Gypsum is used for making building plaster and wallboard tiles, as an absorbent for chemicals, as a paint pigment and extender, and for coating papers. Natural gypsum of California, containing 15%–20% sulfur, is used for producing ammonium sulfate for fertilizer. Gypsum is also used to make sulfuric acid by heating to 1093°C in an air-limited furnace. The resultant calcium sulfide is reacted to yield lime and sulfuric acid. Raw gypsum is also used to mix with portland cement to retard the set. Compact massive types of the mineral are used as building stones. The color is naturally white, but it may be colored by impurities to gray, brown, or red. The specific gravity is 2.28–2.33 and the hardness 1.5–2. It dehydrates when heated to about 190°C, forming the hemihydrate $2\text{CaSO}_4 \cdot \text{H}_2\text{O}$, which is the basis of most gypsum plasters. It is called calcined gypsum, or when used for making ornaments or casts, it is called plaster of Paris. When mixed with water, it again forms the hydrated sulfate that will solidify and set firmly owing to interlocking crystallization. Theoretically, 18% of water is needed for mixing, but actually more is necessary. Insufficient water causes cracking. Water solutions of synthetic resins are mixed with gypsum for casting strong, waterproof articles.

Much calcined gypsum, or plaster of Paris, is used as gypsum plaster for wall finish. For such use, it may be mixed in lime water or glue water and with sand. Because of its solubility in water, it cannot be used for outside work.

The presence of halite (NaCl) or other sulfates in the solution lowers this temperature, although metastable gypsum exists at higher temperatures.

Crystals of gypsum are commonly tabular, diamond shaped, or lenticular; swallow-tailed twins are also common. The mineral is monoclinic with symmetry 2/m. Gypsum is the index mineral chosen for hardness 2 on the Mohs scale. In addition to free crystals, the common forms of gypsum are satin spar (fibrous), alabaster (finely crystalline), and selenite (massive crystalline).

Gypsum is used for a variety of purposes, but chiefly in the manufacture of plaster of Paris, in the production of wallboard, in agriculture to loosen clay-rich soils, and in the manufacture of fertilizer. Plaster of Paris is made by heating gypsum to 200°C in air.

Gypsum deposits play an important role in the petroleum industry. The organic material commonly associated with its formation is considered a source of hydrocarbon (oil and gas) generation. In addition, these deposits act as a seal for many petroleum reservoirs, preventing the escape of gas and oil.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

H

Habit Plane

The plane or system of planes of a crystalline phase along which some phenomenon, such as twinning or transformation, occurs. See *crystal structure*.

Hackle

(1) A line on a glass crack surface, running parallel to the local direction of cracking, separating parallel but noncoplanar portions of the crack surface. (2) A finely structured fracture surface marking that gives a matte or roughened appearance to the surface, having varying degrees of coarseness. Finely structured hackle is variously known as fine hackle, frosted area, gray area, matte, mist, and stippled area. Coarsely structured hackle is also known as *striation*. See also *mist hackle*, *shear hackle*, *twist tackle*, and *wake hackle*.

Hackle Marks

Fine ridges on the fracture surface of a glass, parallel to the direction of propagation of the fracture.

Hackle Surface

A rough textured surface characteristic of the fast tensile failure of brittle metals.

Hadfield's (Manganese) Steel

An austenitic steel with about 13% manganese and 1.2% carbon. It is tough and wear resistant particularly to gouging abrasion. It is usually quenched from about 1000°C to retain the austenitic phase, in which condition it is relatively soft, about 200 Hv. However, cold deformation such as abrasion induces a local formation of martensite with a hardness of about 600 Hv. See *austenitic manganese steel*.

Hematite

Red iron oxide, Fe_2O_3 .

Hafnium and Alloys

Hafnium (Hf), the heaviest of the three metals comprising the Group IV transition metals, is now in production. Because of the startling similarity in their chemical properties, zirconium and hafnium always occur together in nature. In their respective ability to absorb neutrons, however, they differ greatly and this difference has led to their use and surprisingly different ways in nuclear reactors. Zirconium, with a low neutron absorption cross section (0.18 barn), is highly desirable as a structural material in water-cooled nuclear reactor cores. Hafnium, on the other hand, because of its high neutron absorption cross section (105 barns), can be used as a neutron-absorbing control material in the same nuclear reactor cores. Thus, the two elements, which occur together so intimately in nature that

they are very difficult to separate, are used as individual and important but contrasting components in the course of nuclear reactors.

Properties

Pure hafnium is a lustrous, silvery metal that is not so ductile nor so easily worked as zirconium; nevertheless, hafnium can be hot- and cold-rolled on the same equipment and with similar techniques as those used for zirconium. All zirconium chemicals and alloys may contain some hafnium, and hafnium metal usually contains about 2% zirconium. The melting point, 2222°C, is higher than that of zirconium, and heat-resistant parts for special purposes have been made by compacting hafnium powder to a density of 98%. The metal has a close-packed hexagonal structure. The electric conductivity is about 6% that of copper. It has excellent resistance to a wide range of corrosive environments.

Hafnium Alloys and Compounds

Hafnium forms refractory compounds with carbon, nitrogen, boron, and oxygen. Hafnium oxide or hafnia, HfO_2 , is a better refractory ceramic than zirconia but is costly.

Hafnium carbide, HfC , produced by reacting hafnium oxide and carbon at high temperature, is obtained as a loosely coherent mass of blue-black crystals. The crystals have a hardness of 2910 Vickers and a melting point of 4160°C. It is thus one of the most refractory materials known. Heat-resistant ceramics are made from hafnium titanate by pressing and sintering the powder. The material has the general composition $x(\text{TiO}_2) \cdot n(\text{HfO}_2)$, with varying values of x and n . Parts are made with 18% titania and 82% hafnia have a density of 7.197 kg/m^3 , a melting point of about 2204°C, a low coefficient of thermal expansion, good shock resistance, and a rupture strength above 68 MPa at 1093°C. Hafnium nitride, with a melting point of 3300°C, has the highest melting point of any nitride and hafnium boride and, with a melting point of 3260°C, has a melting point higher than any other boride. The alloy Ta_4HfC_5 has the highest melting point of any substance known, about 4215°C.

Hair

The fibrous covering of skins of various animals, used for making coarse fabrics and for stuffing purposes. It is distinguished from wool in having no epidermal scales. It cannot be spun readily, although certain hairs such as camel hair are noted for great softness and can be made into fine fabrics. *Horsehair* is from the manes and tails and is used as a brush fiber and for making hair-cloth. It is largely imported from China and Argentina, cleaned and sorted. The imported hair from live animals is more resilient than domestic hair from dead animals. *Cattle hair* is taken from slaughtered animals in packing plants. The body hair is used as a binder in plaster and cements, for hair felt, and for stuffing. The tail hair is used for upholstery, filter cloth, and stuffing. The *ear hair* is used for brushes. It has a strong body and fine, tapered point suitable for poster brushes. In the brush industry, it is known as *ox hair*.

H

Artificial horsehair, or *monofil*, is a single-filament cellulose acetate fiber, used for braids, laces, hairnets, rugs, and pile fabrics. *Haircloth* is a stiff, wiry fabric with a cotton or linen wrap and a filling of horsehair. It is elastic and firm and is used as a stiffening and interlining material. The colors are black, gray, and white. The fabric is difficult to weave and disintegrates easily, as the hairs cannot be made into a single strand and must be woven separately. *Press cloth*, used for filtering oils, was made from human hair, which has high tensile strength, resiliency, and resistance to heat. The hair came from China, but filter fabrics are now made from synthetic fibers. *Rabbit hair* from Europe and Australia is used for making felt hats and is referred to as *rabbit fur*, although it does not felt as wool does. The white rabbit hair known as *Angora wool* is from the Angora rabbit of France and Belgium, called *Belgian hare*. The hairs are clipped or plucked four times a year when they are up to 3 in. (8 cm) long. They are soft and lustrous, dye easily to delicate shades, and are used for soft wearing apparel. Because of its fluffiness and hairy characteristics, the wool is difficult to spin and is usually employed in mixtures.

Hair Grease

A grease containing horsehair or wool fiber.

Hairline Cracks

Fine cracking particularly those due to hydrogen damage. See *flake*.

Hairline Craze

Multiple fine surface separation cracks in composites that exceed ¼ in. (6 mm) in length and do not penetrate in depth the equivalent of a full ply of reinforcement. See also *crazing*.

Half Cell

An *electrode* immersed in a suitable *electrolyte*, designed for measurements of *electrode potential*.

Half Hard

A *temper* of nonferrous alloys and some ferrous alloys characterized by tensile strength about midway between those of *dead soft* and *full hard tempers*.

A grade of copper or other nonferrous material. Many such materials are obtainable in various strength levels achieved by varying the severity of the final cold work operation. As the amount of work increases, so does the hardness and strength, leading to terms such as quarter hard, half hard, and full hard.

Half Journal Bearing

A journal bearing extending 180° around a journal.

Half-Life ($t_{1/2}$)

The time required for one-half of an initial (large) number of atoms of a radioactive isotope to decay. Half-life is related to the decay constant λ . By the expression $t_{1/2} = \ln 2/\lambda$. See also *decay constant*.

Half Thickness

The thickness of material that reduces the level of radioactivity by one half. It may be expressed as thickness, that is, mm, or weight per unit area, that is, g/cm².

Halides

Fluorides, chlorides, bromides, iodides, and astatides.

Hall Effect

The phenomenon whereby a current-carrying conductor in a magnetic field develops a charge perpendicular to the plane containing the conductor and the field.

Hall-Petch Relationship

The relationship between the grain size and yield strength.

$$\text{Yield strength} = \sigma_0 + kd$$

where

d is the average grain size

k and σ_0 are constants for the material

Typically, the yield strength is inversely proportional to the square root of the grain size.

Hall Process

A commercial process for winning aluminum from alumina by electrolytic reduction of a fused bath of alumina dissolved in cryolite.

Halocarbon Plastics

Plastics based on resins made by the polymerization of monomers composed only of carbon and a halogen or halogens.

Halogen

Any of the elements of the halogen family, consisting of fluorine, chlorine, bromine, iodine, and astatine.

Hammer

A machine that applies a sharp blow to the work area through the fall of a ram onto an anvil. The ram can be driven by gravity or power. See also *gravity hammer* and *power-driven hammer*.

Hammer Forging

Forging in which the work is deformed by repeated blows. Compare with *press forging*.

Hammering

The working of metal sheet into a desired shape over a form or on a high-speed hammer and a similar anvil to produce the required dishing or thinning.

Hammer Welding

Forge welding by hammering.

Hand Brake

A small manual folding machine designed to bend sheet metal, similar in design and purpose to a press brake.

Hand Forge (Smith Forge)

A forging operation in which forming is accomplished on dies that are generally flat. The piece is shaped roughly to the required contour with little or no lateral confinement; operations evolving mandrels are included. The term hand forge refers to the operation performed, while hand forging applies to the part produced.

Hand Lay-Up

In composite processing, it is the process of manually placing (and working) successive plies of reinforcing material or resin-impregnated reinforcement in position on a mold.

Handling Brakes

Irregular *brakes* caused by improper handling of metal sheets during processing. These brakes result from bending or sagging of the sheets during handling.

Handling Strength

A low level of strength initially obtained by an adhesive that allows specimens to be handled, moved, or unclamped without causing disruption of the curing process or affecting bond strength.

Hand Straightening

A straightening operation performed on a surface plate to bring a forging within straightness tolerance. A bottom die from a set of finish dies is often used instead of a surface plate. Hand tools used include mallets, sledges, blocks, jacks, and oil gear presses in addition to regular inspection tools.

Hansgird Process

A process for producing magnesium by reduction of magnesium oxide with carbon.

Hard Chromium

Chromium electrodeposited for engineering purposes (such as to increase the wear resistance of sliding metal surfaces) rather than as a decorative coating. It is usually applied directly to basis metal and is customarily thicker ($>1.2\text{ }\mu\text{m}$ or 0.05 mils) under a decorative deposit, but not necessarily harder.

Hard Drawn

An imprecise term applied to drawn products, such as wire and tubing, that indicates substantial cold reduction without subsequent annealing. Compare with *light drawn*.

Hard-Drawn Copper Wire

Copper wire that has been drawn to size and not annealed.

Hardenability

The relative ability of a ferrous alloy to form martensite when quenched from a temperature above the upper critical temperature. Hardenability is commonly measured as the distance below a quenched surface at which the metal exhibits a specific hardness (e.g., 50 HRC) or a specific percentage of martensite in the microstructure. HRC represents the Rockwell hardness number and 50 HRC is 50 on the Rockwell hardness C scale. See *Rockwell*.

Hardener (Metals)

An alloy rich in one or more alloying elements that is added to a melt to permit closer control of composition than is possible by the addition of pure metals, or to introduce refractory elements not readily alloyed with the base metal. Sometimes called *master alloy* or rich alloy.

Hardener (Plastics)

A substance or mixture added to a plastic composition to promote or control the curing action by taking part in it.

Hardening

Increasing hardness of metals by suitable treatment, usually involving heating and cooling. When applicable, the following more specific terms should be used: *age hardening*, *case hardening*, *flame hardening*, *induction hardening*, *precipitation hardening*, and *quench hardening*.

Hard Face

A seal facing of high hardness that is applied to a softer material, such as by flame spraying, plasma spraying, electroplating, nitriding, carburizing, or welding.

Hard Facings

Hard facing is a technique by which a wear-resistant overlay is welded on a softer and usually rougher base metal. The method is versatile and has a number of advantages:

1. Wear resistance can be added exactly where it is needed on the surface.
2. Hard compounds and special alloys are easy to apply.
3. Hard facings can be applied in the field as well as in the plant.
4. Expensive alloying elements can be economically used.
5. Protection can be provided in depth.
6. A unique and useful structure is provided by the hard-surfaced, tough-core composite.

Many of the merits of hard facing stem from the hardness of the special materials used. For example, ordinary weld deposits range in hardness up to about 200 Brinell, hardened steels have a hardness up to 700–800 Vickers, and special carbides have a hardness of to about 3000 Vickers. However, it is important to note that the hardness of the materials does not always correlate with wear resistance. Thus, special tests should be performed to determine the resistance of the material to impact, gouging abrasion, grinding (high-stress abrasion), erosion (low-stress scratching abrasion), seizing or galling, and hot wear.

H

Another important point is that durable overlays are not necessarily hard. Most surfacing is used to protect base metals against abrasion, friction, and impact. However, many *hard facings* such as the stainless steels, related nickel-base alloys, and copper alloys are used for corrosion-resistant applications where hardness may not be a factor. Also, the relatively soft leaded bronzes may be used for bearing surfaces. Other facings are also used for heat- and oxidation-resistant applications.

Methods of Application

Hard facings can be applied by

1. Manual, semiautomatic, and automatic method using bare or flux-coated electrodes
2. Submerged arc welding
3. Inert-gas shielded arc welding (both consumable and tungsten electrode types)
4. Oxyacetylene and oxyhydrogen gas welding
5. Metal spraying
6. Welded or brazed on inserts

Gas welding and spraying usually provide higher quality and precise placement of surfaces; arc welding is less expensive. Automatic or semiautomatic methods are preferred where large areas are to be covered, or where repetitive operations favor automation.

Surfacing filler metals are available in the form of drawn wire, cast rods, powders, and steel tubes filled with ferroalloys or hard compounds (e.g., tungsten carbide). The electrodes may take the form of filled tubes or alloyed wires, stick types, or coils specially designed for automated operations. The stick-type electrodes may have a simple steel core and a thick coating containing the special alloys. In submerged arc welding, the alloys may be introduced through a special flux blanket. In spray coating, the materials are used in the form of powders or bonded wire.

Sprayed facings are advantageous in producing thin layers and in following surface contours. With this method, it is usually necessary to fuse the sprayed layer in place after deposition to obtain good abrasion resistance. However, under boundary lubrication conditions, the as-sprayed porosity of the facings may aid against frictional wear.

Hard facings are used in thicknesses from 0.031 to 25.4 cm or more. The thinnest layers are usually deposited by gas welding, usually with low-melting alloys that solidify with many free carbide or other hard compound crystals. The thick deposits are usually made from air-hardening or austenitic steels.

Hard overlays are usually strong in compression but weak in tension. Thus, they perform better in pockets, grooves, or low ridges. Edges and corners must be treated cautiously unless the deposit is tough. Brittle overlay should be deposited over a base of sufficient strength to prevent subsurface flow under excessive compression.

Gas welding is a useful method for depositing small, precisely located surfacings in applications where the base metal can withstand the welding temperatures (e.g., steam valve trim and exhaust valve facings). On the other hand, heavy layers and large areas may be impossible to surface without cracks with the harder, more wear-resistant alloys because of the severe thermal stresses that are encountered (e.g., usually in arc welding). Thus, the opposing factors of wear resistance and freedom from cracking frequently require a compromise in process and material selection.

Materials

Basically, hard-facing materials are alloys that lend themselves to weld fusion and provide hardness or other properties without special heat

treatment. Thus, for hard surfacing, the steels and the matrices of high-carbon irons contain enough alloys to cause the hardening transformation during weld cooling, rather than after a quenching treatment.

The properties of the iron-, nickel-, and cobalt-base alloys are strongly affected by carbon content and somewhat by the welding technique used. For example, gas welding usually provides superior abrasion resistance, although carbon pickup may lower corrosion resistance. Arc welding tends to burn out carbon and alloys, thereby lowering abrasion resistance but increasing toughness; high thermal stresses from arc welding may also accentuate cracking tendencies.

The martensitic irons, martensitic steels, and austenitic manganese steels are suited for light-, medium-, and heavy-impact applications, respectively. Gouging abrasion applications usually require an austenitic manganese steel because of the associated heavy impact. Grinding abrasion is well resisted by the martensitic irons and steels. Erosion is most effectively resisted by a good volume of the very hard compounds (e.g., high-chromium irons). Tungsten carbide composites have outstanding resistance to abrasion where heavy impact is not present, but deposits may develop a rough surface.

Selection of materials for hot-wear applications is complicated by oxidation, tempering, softening, and creep factors. Oxidation resistance is provided by using a minimum of 25% chromium. Tempering resistance (up to 593°C) is provided by chromium, molybdenum, tungsten, etc. Creep resistance is provided by the austenitic structure and nickel- or cobalt-bearing alloys. The chromium-cobalt-tungsten grade of materials usually provides a good combination of properties above 649°C.

Hard Head

A hard, brittle, white residue obtained in refining of tin by liquation, containing, among other things, tin, iron, arsenic, and copper. Also a refractory lump of ore, only partly smelted.

Hard Metal

A collective term that designates a sintered material with high hardness, strength, and wear resistance and is characterized by a tough metallic binder phase and particles of carbides, borides, or nitrides of the refractory metals. The term is in general use in Europe, while for the carbides, the term “cemented carbides” is preferred in the United States, and the boride and nitride materials are usually categorized as cermets.

Hardness

A measure of the resistance of a material to surface indentation or abrasion; may be thought of as a function of the stress required to produce some specified type of surface deformation. There is no absolute scale for hardness; therefore, to express hardness quantitatively, each type of test has its own scale of arbitrarily defined hardness. Indentation hardness can be measured by *Brinell*, *Rockwell*, *Vickers*, *Knoop*, and *scleroscope hardness tests*.

Hardness Profile

Hardness as a function of distance from a fixed reference point (usually from the surface).

Hardness Satin

A fabric weaving pattern producing a satin appearance. See also *eight-hardness satin* and *four-hardness satin*.

Hard Rubber

Hard rubber is a plastic. It is a resinous material mixed with a polymerizing or curing agent and fillers and can be formed under heat and pressure to practically any desired shape.

The bulk of today's hard rubber is made with SBR (styrene-butadiene rubber) synthetic rubber. Other types of synthetic rubbers, such as butyl or nitrile or, in rare cases, silicone or polyacrylic, can also be used.

Once it has gone through the process of heat and pressure, hard rubber cannot be returned to its original state and therefore falls into the class of thermosetting plastics, that is, those that undergo chemical change under heat and pressure. It differs, however, from other commercial thermosetting plastics such as the phenolics and ureas and that after it has gone through the thermosetting process it will still soften somewhat under heat. In this characteristic, it mostly resembles the thermoplastic acetates, polystyrenes, and vinyls. It differs from all others in that it is available in pliable sheet form before vulcanization and is therefore adaptable to many shapes for which molds and presses are not necessary. Because of this feature and because it can be softened again after vulcanization, it falls into a class by itself in the field of plastics.

The term "hard rubber" is self-descriptive. The hardness is measured on the Shore D scale, which is several orders of magnitude higher than the Shore A scale used for conventional rubbers and elastomers. Similar in composition to soft rubber, it contains a much higher percentage of sulfur, up to a saturation point of 47% of the weight of the rubber in the compound. If sulfur is present rubber compounds in amounts over 18% of the weight of rubber in the compound when the material is completely vulcanized, the product will be generally known as hard rubber.

Properties and Fabrication

The most important properties of hard rubber are the combination of relatively high tensile strength, low elongation, and extremely low water absorption.

Hard rubber may be compression-, transfer-, or injection-molded. In sheet form it can be hand-fabricated into many shapes. Its machining qualities are comparable to brass, and it may be drilled and tapped. The material lends itself readily to permanent or temporary sealing with hot or cold cements and sealing compounds.

The size and shape of a hard rubber part are dependent only upon the size of press equipment and vulcanizers available.

Uses

Perhaps the largest application for hard rubber is in the manufacture of battery boxes. The water-meter industry is also a large user. Hard rubber linings in coatings either molded or hand laid-up account for large amounts of material. In the electrical industry, hard rubber is used for terminal blocks, insulating materials, and connector protectors. The chemical, electroplating, and photographic industries use large quantities of hard rubber for acid-handling devices.

Hard Solder

A term used erroneously to denote silver-base brazing filler metals.

Hard-Surfaced Polymers

Polymers, developed at the U.S. Department of Energy's Oak Ridge National Laboratories, which combine the flexibility and corrosion

resistance of plastics with the strength and durability of metals. They are made by high-energy ion-beam irradiation, which displaces some atoms while ionizing others, forming new bonds in creating a highly cross-linked microstructure of much greater hardness, wear resistance, and abrasion resistance. Chemical resistance and oxidation resistance are also improved.

Hard Surfacing

See preferred terms *surfacing* or *hard facing*.

Hard Temper

Same as *full hard temper*.

Hard Water

Water that contains certain salts, such as those of calcium or magnesium, which form insoluble deposits in boilers and form precipitates with soap.

Haring Cell

A four-electrode cell for measurement of electrolyte resistance and electrode polarization during electrolysis.

Hartmann Lines

See *Lüders lines*.

Haze

Cloudy appearance under or on the surface of a plastic, not describable by the terms *chalking* or *bloom*.

H-Band Steel

Carbon, carbon-boron, or alloy steel produced to specified limits of hardenability; the chemical composition range may be slightly different from that of the corresponding grade of ordinary carbon or alloy steel.

HDPE

See *high-density polyethylene*.

Header

See *upsetter*.

Heading

The upsetting of wire, rod, or bar stock in dies to form parts that usually contain portions that are greater in cross-sectional area than the original wire, rod, or bar.

Head-to-Head

On a polymer chain, a type of configuration in which the functional groups are on adjacent carbon atoms.

H

Head-to-Tail

On a polymer chain, a type of configuration in which the functional groups or adjacent polymers are as far apart as possible.

Healed-over Scratch

A scratch in a metallic object that occurred in an earlier mill operation and was partially masked in subsequent rolling. It may open up during forming.

Hearth

The bottom portions of certain furnaces, such as blast furnaces, air furnaces, and other reverberatory furnaces, that support the charge and sometimes collect and hold molten metal.

Heat

A stated tonnage of metal obtained from a period of continuous melting in a cupola or furnace, or the melting period required to handle this tonnage.

Heat-Activated Adhesive

A dry adhesive that is rendered tacky or fluid by application of heat, or heat and pressure, to the assembly.

Heat-Affected Zone (HAZ)

That portion of the base metal that was not melted during brazing, cutting, or welding but whose microstructure and mechanical properties were altered by the heat.

Heat Buildup

In processing of plastics, the rise in temperature in a part resulting from the dissipation of applied strain energy as heat or from applied mold cure heat. See also *hysteresis*.

Heat Check

A pattern of parallel surface cracks that are formed by alternate rapid heating and cooling of the extreme surface metal, sometimes found on forging dies and piercing punches. There may be two sets of parallel cracks, one set perpendicular to the other.

Heat Checking

A process in which fine cracks are formed on the surface of a body in sliding contact due to the buildup of excessive frictional heat.

Heat Cleaned

A condition in which glass or other fibers are exposed to elevated temperatures to remove preliminary sizings or binders not compatible with the resin system to be applied.

Heat-Deflection Temperature

The temperature at which a standard plastic test bar deflects a specified amount under a stated load. Now called deflection temperature under load (DTUL).

Heat-Disposable Pattern

In foundry practice, a *pattern* formed from a wax- or plastic-base material that is melted from the mold cavity by the application of heat.

Heat Distortion

Distortion or flow of a material or configuration due to the application of heat.

Heat Distortion Point

The temperature at which a standard plastic test bar deflects a specified amount under a stated load. Now called deflection temperature.

Heat-Fail Temperature

The temperature at which delamination of an adhesively bonded structure occurs under static loading and shear.

Heat Forming

See *thermoforming*.

Heat Insulators

Materials having high resistance to heat rays, or low heat conductivity, used as protective insulation against either hot or cold influences. The materials are also called "thermal insulators." Insulators for extremely high external temperatures, as on aerospace vehicles, are of ablative materials. Efficiency of heat insulators is measured relatively in Btu/(h · ft · F) {W/(m · K)}, known as the "K factor." The thermal conductivity of air and gases is low, and the efficiency of some insulators, especially fibrous ones, is partly due to the air-spaces. On the other hand, the thermal conductivity of a porous insulator may be increased if water is absorbed into the spaces.

A wide variety of materials are used as thermal insulators in the form of powder or granules for loose fill, blanket batts of fibrous materials for wall insulation, and sheets or blocks. Although metals are generally high-heat conductors, the polished white metals may reflect as much as 95% of the heat waves and make good *reflective insulators*. But for this purpose the bright surface must be exposed to airspace. Aluminum has a high K factor, up to 130, but crumbled alumina foil is an efficient thermal insulator as a fill in walls. Wool and hair, either loose or as felt, with a K factor of 0.021 are among the best of the insulators, but organic materials are usable only for low temperatures, and they are now largely replaced by mineral wool or ceramic fibers. Mineral wool has a low K factor, 0.0225. *Tipersul*, of DuPont, is a *potassium titanate fiber* used loose or in batts, blocks, or sheets. Its melting point is 2500°F (1371°C), and it withstands continuous temperatures to 2200°F (1204°C). Another ceramic fiber, called *Fibrox*, for the same purpose, is a *silicon oxycarbide*, SiCO, in light, fluffy fibers.

Magnesia or asbestos, or combinations of the two, is much used for insulation of hot pipelines, while organic fibrous materials are used for cold lines. *High-heat insulators*, for furnaces and boilers, are usually made of refractory ceramics such as chromite. For intermediate temperatures, expanded glass, such as *Foamglass* of Pittsburgh-Corning Corp., may be used. Some rigid materials of good structural strength serve as structural parts as well as insulators. *Roofinsul*, used for roof decks, is a lightweight board compressed from wood fibers. *Ludlite board*, of Allegheny

Ludlum Corp., for paneling, is a thin stainless steel backed with a magnesia-asbestos composition. Insulators in sheets, shapes, and other forms are sold under a great variety of trade names. *Dry Zero*, for refrigeration insulation, consists of kapok batts enclosed in fiberboard. *Balsam wool* is wood fibers chemically treated to prevent moisture absorption.

Heat-Resistant Alloys (Cast)

Cast alloys suitable for use at service temperatures to at least 538°C and, for some alloys, to 1093°C are classed as *heat-resistant* or *high-temperature* alloys. They have the characteristic of corroding at very slow rates compared with unalloyed or low-alloy cast iron or steel in the atmospheres to which they are exposed, and they offer sufficient strength at the operating temperature to be useful as load-carrying engineering structures. Iron-base and nickel-base alloys comprise the bulk of production, but cobalt-base, chromium-base, molybdenum-base, and columbium-base alloys are also made.

Although some cast heat-resistant alloys are available in composition similar to wrought alloys, it is necessary to differentiate between them. Cast alloys are made to somewhat different chemical specifications than wrought alloys; physical and mechanical properties for each group are also somewhat different.

For these reasons, it is advisable to follow the alloys designated as the H series by the Alloy Casting Institute of the American Steel Founders Society as well as nickel-base alloys and cobalt-base alloys. Most of the nickel-base and cobalt-base alloys are also known as superalloys because of their exceptional high-temperature stress-rupture strength and creep resistance as well as corrosion and oxidation resistance.

There are, moreover, a number of heat-resistant cast alloys that are not available in wrought form; this is frequently of advantage in meeting special conditions of high-temperature service. In addition to the grades HA to HX discussed later, the industry produces special heat-resistant compositions. Many of these are modifications of the standard types, but some are wholly different and are designed to meet unique service conditions.

Selection of a particular alloy, of course, is dependent upon the application, and in this article the composition, structure, and properties of the various cast heat-resistant alloys are discussed from this point of view.

Proper selection of an alloy for a specific high-temperature service involves consideration of some or all of the following factors: (1) required life of the part, (2) range and speed of temperature cycling, (3) the atmosphere and its contaminants, (4) complexity of casting design, and (5) further fabrication of the casting. The criteria that should be used to compare alloys depend on the factors enumerated, and the designer will be aided in the choice by providing the foundry with as much pertinent information as possible on intended operating conditions before reaching a definite decision to use a particular alloy type.

Physical and Mechanical Properties

For high-temperature design purposes, a frequently used design stress is 50% of the stress that will produce a creep rate of 0.0001%/h maximum operating temperature. Such a value should be applied only under conditions of direct axial static loading and essentially uniform temperature or slow temperature variation. When impact loading or rapid temperature cycles are involved, a considerably lower percentage of the limiting creep stress should be used. In the selection of design stresses, safety factor should be higher if the parts are inaccessible, nonuniformly loaded, or of complex design;

they may be lower if the parts are accessible for replacement, fully supported or rotating, and of simple design with little or no thermal gradient.

H-Series Cast Alloys

The H-series cast alloys include iron-chromium, iron-chromium-nickel, and iron-nickel-chromium alloys also containing 0.20%–0.75% carbon, 1%–2.5% silicon, and 0.35%–2% manganese. A letter (A–X) following the H is used to distinguish alloy compositions more closely. The iron-chromium cast alloys (HA, HC, and HD) contain as much as 30% chromium and under 7% nickel. The iron-chromium-nickel cast alloys (HE, HF, HH, HI, HK, and HL) contain as much as 32% chromium and 22% nickel. And the iron-nickel-chromium cast alloys (HN, HP, HP-50 WZ, HT, HU, HW, and HX) contain as much as 68% nickel (HX) and 32% chromium (HN) so that some of these alloys are actually nickel-base instead of iron-base alloys.

In selecting alloys from this group, the following factors are considered:

1. Increasing nickel content increases resistance to carburization, decreases hot strength somewhat, and increases resistance to thermal shock.
2. Increasing chromium content increases resistance to corrosion and oxidation.
3. Increasing carbon content increases hot strength.
4. Increasing silicon content increases resistance to carburization but decreases hot strength.

All are noted primarily for their oxidation resistance and ability to withstand moderate to severe temperature changes. Most are heat treatable by aging room-temperature tensile properties in the aging condition ranging from 503 to 793 MPa in terms of ultimate strength, 297–552 MPa in yield strength, and 4%–25% in elongation. Hardness of the aged alloys ranges from Brinell 185 to 270. Applications include heat-treating fixtures, furnace parts, oil-refinery and chemical processing equipment, gas turbine components, and equipment used in manufacturing steel, glass, and rubber.

Both the nickel-base and cobalt-base alloys are probably best known for their use in aircraft turbine engines for disks, blades, vanes, and other components. The nickel alloys contain 50%–75% nickel and usually 10%–20% chromium and substantial amounts of cobalt, molybdenum, aluminum, and titanium and small amounts of zirconium, boron, and, in some cases, hafnium. Carbon content ranges from less than 0.1% to 0.20%. Because of their complex compositions, they are best known by trade names, such as B-1900; Hastelloy X; IN-100, IN-738X, and IN-792; Rene 77, Rene 80, and Rene 100; Inconel 713C, Inconel 713 L C, Inconel 718, and Inconel X-750; MAR-M 200, MAR-M 246, and MAR-M 247; Udimet 500, Udimet 700, and Udimet 710; and Waspaloy. The high-temperature strength of most of these alloys is attributed to the presence of refractory metals, which provide solid solution strengthening; the presence of grain-boundary-strengthening elements, such as carbon, boron, hafnium, and zirconium; and, because of the presence of aluminum and titanium, strengthening by precipitation of an $\text{Ni}_3(\text{Al}, \text{Ti})$ compound known as “gamma prime” during age hardening. Many of these alloys provide 1000 h stress-rupture strengths in the range of 690–759 MPa at 649°C and 55–124 MPa at 982°C.

The cobalt alloys contain 36%–65% cobalt, usually more than 50%, and usually about 20% chromium and substantial amounts of nickel, tungsten, tantalum, molybdenum, iron and/or aluminum and small amounts of still other ingredients. Carbon content is

H

0.05%–1% Erie, although not generally as strong as the nickel alloys, some may provide better corrosion and oxidation resistance at high temperatures. These alloys include L-605; S-816; V-36; WI-52; X-40; J-1650; Haynes 21 and Haynes 151; AiResist 13, AiResist 213, and AiResist 215; and MAR-M 302, MAR-M 322, and MAR-M 918. Their 1000 h stress-rupture strengths range from about 276 to 483 MPa at 649°C and from about 28 to 103 MPa at 982°C.

Heat-Resistant Plastics (Superpolymers)

Several different plastics developed in recent years that maintain mechanical and chemical integrity above 204°C for extended periods are frequently referred to as superpolymers. They are polyimide, polysulfone, polyphenylene sulfide, polyarylsulfone, and aromatic polyester.

In addition to their high-temperature resistance, all these materials have in common high strength and modulus and excellent resistance to solvents, oils, and corrosive environments. They are also among the highest-priced plastics, and a major disadvantage is processing difficulty. Molding temperatures and pressures are extremely high compared with conventional plastics. Some of them, including polyimides and aromatic polyester, are not molded conventionally. Because they do not melt, the molding process is more of a sintering operation. Because of their high price, suprapolymers are largely used in specialized applications in the aerospace and nuclear energy field.

Indicative of their high-temperature resistance, the superpolymers have a glass transition temperature well over 260°C as compared to less than 177°C for most conventional plastics. In the case of polyimides, the glass temperature is greater than 427°C, and the material decomposes rather than softens when heated excessively.

Polysulfone has the highest service temperature of any melt-processable thermoplastic. Its flexural modulus stays above 2040 MPa at up to 160°C. At such temperatures, it does not discolor or degrade.

Aromatic polyester does not melt, but at 427°C can be made to flow in a nonviscous manner similar to metals. Thus, filled and unfilled forms and parts can be made by hot sintering, high-velocity forging, and plasma spraying. Notable properties are high thermal stability, good strength at 316°C, high thermal conductivity, good wear resistance, and extrahigh compressive strength.

Heat Sealing

A method of joining plastic films by simultaneous application of heat and pressure to areas in contact.

Heat-Sealing Adhesive

A thermoplastic film adhesive that is melted between the adherend surfaces by heat application to one or both of the surfaces.

Heat Shock

A test to determine the stability of a material by sudden exposure to a significantly higher or lower temperature for a short period of time.

Heat Sink

A material that absorbs or transfers heat away from a critical element or part.

Heat Time

In resistance welding, the time that the current flows during any one impulse.

Heat Tinting

Coloration of a metal surface through oxidation by heating to reveal details of the microstructure.

Heat Transfer

Flow of heat by conduction, convection, or radiation.

Heat-Transfer Agents

Liquids or gases used as intermediate agents for the transport of heat or cold between the heat source in the process, or for dissipating heat by radiation. Water, steam, and air are the most common heat-transfer agents, but the term is usually applied only to special materials. Air can be used over the entire range of industrially important temperatures, but it is a poor heat-transfer medium. Water can be used only between its freezing and boiling points, unless high pressures are employed to keep the water liquid. A liquid agent should have a wide liquid range, be noncorrosive and nontoxic, and have low vapor pressure to minimize operational loss.

Gallium, with a freezing point of 85.6°F (29°C) and boiling point of 3600°F (1982°C), offers an exceptionally wide liquid range; but it is too costly for ordinary use, and in the liquid metal it also attacks other metals. Mercury is used for heat transfer but is costly and toxic, and at 1200°F (649°C), it exerts a vapor pressure of 500 lb/in.² (3.4 MPa). Among commercial products, the heat-transfer fluid spans the range in chemical structure from *alkylated benzenes*, *alkylated biphenyls*, *alkylated naphthalenes*, *unhydrogenated polyphenols*, *benzylated aromatics*, *diphenyl-diphenyl oxide eutectics*, *polyalkylene glycols*, *dicarboxylic acid esters*, *polymethyl siloxanes*, *mineral oils*, and inorganic nitrate salts.

Brine solutions of sodium or calcium chlorides are used for heat transfer for temperatures down to –6°F (–21°C), but are corrosive to metals. Molten sodium and potassium salts are used for temperatures from 1112°F to 2552°F (600°C–1400°C), but are corrosive to metals.

Heat-Treatable Alloy

An alloy that can be hardened by heat treatment.

Heat-Treating Film

A thin coating or film, usually an oxide, formed on the surface of a metal during heat treatment.

Heat Treatment

Heating and cooling a solid metal or alloy in such a way as to obtain desired conditions or properties. Heating for the sole purpose of hot working is excluded from the meaning of this definition.

Heavy Alloy

This is a name applied to tungsten–nickel alloy produced by pressing and sintering the metallic powders. It is used for screens for

x-ray tubes and radioactivity units, for contact surfaces for circuit breakers, and for balances for high-speed machinery. The original composition was 90% tungsten and 10% nickel, but a proportion of copper is used to lower sintering temperature and give better binding as the copper wets the tungsten. Too large a proportion of copper makes the product porous. In general, the alloys weigh nearly 50% more than the last, permitting space-saving in counterweights and balances, and they are more efficient as gamma-ray absorbers than lead. They are highly heat resistant, retain a tensile strength of about 137 MPa at 1093°C, have an electric conductivity about 15% that of copper, and can be machined and brazed with silver solder.

An alloy of 90% tungsten, 7.5% nickel, and 2.5% copper has a tensile strength of 930 MPa, elongation 15%, Rockwell hardness C30, and weight of 16.885 kg/m³. *Kenertium* has this composition. *Fansteel 77 metal* contains 89% tungsten, 7% nickel, and 4% copper. Specific gravity is 16.7, tensile strength 586 MPa, elongation 17%, and Brinell hardness 280. The coefficient of expansion is low, 6.5×10^{-6} K⁻¹. *Heavy metal powder*, for making parts by powder metallurgy, is prealloyed with the tungsten in a matrix of copper–nickel to prevent settling out of the heavy tungsten.

Heavy-Duty Oil

An oil that is stable against oxidation, protects bearings from corrosion, and has detergent and dispersant properties. Heavy-duty oils are suitable for use in gasoline and diesel engines.

Heel

Synonymous with *base*.

Heel Block

A block or plate usually mounted on or attached to a lower die in a forming or forging press that serves to prevent or minimize the deflection of punches or cams.

Helical Winding

In filament-wound items, a winding in which a filament band advances along a helical path, not necessarily at a constant angle, except in the case of a cylinder.

Helium

Helium is a colorless, odorless, elementary gas, He, with a specific gravity of 0.1368, liquefying at –268.9°C, freezing at –272.2°C. It has a valency of zero and forms no electron-bonded compounds. It has the highest ionization potential of any element. The lifting power of helium is only 92% that of hydrogen, but it is preferred for balloons because it is inert and nonflammable and is used in weather balloons. It is also used instead of air to inflate large tires for aircraft to save weight. Because of its low density, it is also used for diluting oxygen in the treatment of respiratory diseases. Its heat conductivity is about six times that of air, and it is used as a shielding gas in welding and in the vacuum tube of electric lamps. Because of its inertness, helium can also be used to hold free chemical radicals, which, when released, give high energy and thrust for missile propulsion. When electric current is passed through helium, it gives a pinkish-violet light and is thus used in advertising signs. Helium can be obtained from atmospheric nitrogen but comes chiefly from natural gas.

Properties

Helium has the lowest solubility in water than any known gas. It is the least reactive element. The density and the viscosity of helium vapor are low. Thermal conductivity and heat content are exceptionally high. Helium can be liquefied, but its condensation temperature is the lowest of any known substance. At pressures below 2.5 MPa, helium remains liquid even at absolute zero.

Applications

Gases

Helium was first used as a lifting gas in balloons and dirigibles. This use continues for high-altitude research and for weather balloons.

Welding

The principal use of helium is in inert gas–shielded arc welding. Using helium instead of argon permits a greater heat release, which is useful in welding very heavy sections or in high-speed machine welding of long seams. By mixing helium and argon, the optimum heat release can be obtained for different welding jobs.

Superconductive Devices

The greatest potential for helium use continues to emerge from extremely-low-temperature applications. Helium is the only refrigerant capable of reaching temperatures below 14 K. In the laboratory many fundamental properties of matter are studied at temperatures near absolute zero with helium refrigeration. Infrared detectors and masers operate with exceptionally low noise distortion at these low temperatures. The chief value of ultralow temperature is a development of the state of superconductivity, in which there is virtually zero resistance to the flow of electricity. Very large currents are carried by even small conductors with little loss of voltage. Electromagnets producing immensely powerful magnetic fields can be made small and light and are energized with modest amounts of electric power through the use of superconducting windings. These magnets are already used in particle accelerators, bubble chambers, and plasma confinement for nuclear physics research. Thermonuclear and magnetohydrodynamic (MHD) power plants are expected to use superconducting magnets. Additional applications are electric motors and generators. Superconductive devices make highly sensitive detectors of electric voltage and frequency, magnetic field strength, and temperature, especially at low-temperature levels.

Lasers

Helium is also used in gas-discharge lasers. Energy is transferred by helium to the lasing gas, carbon dioxide, or neon, for example.

Rockets

Consumption of helium as a pressurizing gas in liquid-fueled rockets declined with the completion of the Apollo space program. Because it is light, inert, and relatively insoluble in the fuel and oxidizer fluids, helium is an ideal material to fill the tankage as the liquids are consumed.

Breathing Mixtures

Use of helium–oxygen breathing mixtures for divers at great depths is required to eliminate the narcotic effects of nitrogen. The low density and low viscosity of helium also reduce the work of breathing. Similarly, helium–oxygen breathing mixtures promote both intake of oxygen and removal of carbon dioxide for persons whose breathing passages are constricted.

H

Nuclear Reactors

Inertness and heat-transfer capability make helium an excellent working fluid for gas-cooled nuclear power reactors. Because the reactor core is composed of graphite and ceramic materials, very high temperatures can be attained without damage. Helium-cooled reactors operate with the highest efficiency of all reactor types. In addition to electric power generation, with helium, working fluid nuclear reactors can provide the process heat for coal gasification, steelmaking, and various chemical processes.

Chemical Analysis

Helium is the most frequently used carrier gas for chemical analysis by gas chromatography. It is the most sensitive leak detection fluid and can be used at extremes of high and low temperature.

Hematite

(1) An iron mineral crystallizing in the rhombohedral system; the most important ore of iron. (2) An iron oxide, Fe_2O_3 , corresponding to an iron content of approximately 70%. Also known as red hematite, red iron ore, and rhombohedral iron ore.

Hemming

A bend of 180° made in two steps. First, a sharp-angle bend is made; next, the bend is closed using a flat punch and a die.

Henry

An electrical unit denoting the inductance of a circuit in which a current varying at the rate of 1 A/s produces an electromotive force of 1 V.

HERF

A common abbreviation for *high-energy-rate forging* or *high-energy-rate forming*.

Hermetic

Sealed so that the object is gastight. The test for hermeticity is to fill the object with a test gas, often helium, and observe leak rates when the object is placed in a vacuum. Plastic encapsulation is not hermetic because it allows permeation by gases.

Herringbone Bearing

Any plain, sleeve, or thrust bearing with herringbone-shaped oil grooves.

Herringbone Pattern

Same as *chevron pattern*.

Hertz

A designation of electrical frequency that denotes cycles per second. Abbreviated Hz.

Hertzian Cone Crack

See *percussion cone*.

Hertzian Contact Area

(1) The contact area (also, diameter or radius of contact) between two bodies calculated according to Hertz's equations of elastic deformation. (2) The apparent area of contact between two nonconforming solid bodies pressed against each other, as calculated from Hertz's equations of elastic deformation.

Hertzian Contact Pressure

(1) The pressure at a contact between two solid bodies calculated according to Hertz's equations of elastic deformation. (2) The magnitude of the pressure at any specified location in a Hertzian contact area, as calculated from Hertz's equations of elastic deformation.

Hertzian Stress

See *contact stress*.

Heterogeneity

The degree of nonuniformity of composition or properties. Compare with *homogeneity*.

Heterogeneous

Of a body of material or matter, comprised of more than one phase (solid, liquid, and gas) separated by boundaries; similarly of a solid, comprised of more than one chemical, crystalline, and/or glassy species, separated by boundaries.

Heterogeneous Equilibrium

In a chemical system, a state of dynamic balance among two or more homogeneous phases capable of stable coexistence in mutual or sequential contact.

Heterogeneous Nucleation

In the crystallization of polymers, the growth of crystals on vessel surfaces, dust, or added nucleating agents.

Heyn Stresses

Same as *microscopic stresses*.

Hexa

An abbreviated form of hexamethylenetetramine, a source of reactive methylene for curing *novolacs*.

Hexagonal (Lattices for Crystals)

Having two equal coplanar axes, a_1 and a_2 , at 120° to each other and the third axis, c , at right angles to the other two; c may or may not equal a_1 and a_2 .

Hexagonal Close-Packed

(1) A structure containing two atoms per unit cell located at (0, 0, 0) and (1/3, 2/3, 1/2) or (2/3, 1/3, 1/2). (2) One of the two ways in which

spherical objects can be most closely packed together so that the close-packed planes are alternately staggered in the order A-B-A-B-A-B. See the term *unit cell*.

High Aluminum Defect

An α -stabilized region in titanium containing an abnormally large amount of aluminum that may span a large number of β grains. It contains an inordinate fraction of primary α , but has a microhardness only slightly higher than the adjacent matrix. Also termed type II defects.

High-Conductivity Copper

Copper that, in the annealed condition, has a minimum electrical conductivity of 100% IACS as determined by ASTM test methods.

High-Cycle Fatigue

Fatigue that occurs at relatively large numbers of cycles. The arbitrary, but commonly accepted, dividing line between high-cycle fatigue and *low-cycle fatigue* is considered to be about 10^4 – 10^5 cycles. In practice, this distinction is made by determining whether the dominant component of the *strain* imposed during cyclic loading is elastic (high cycle) or plastic (low cycle), which in turn depends on the properties of the metal and on the magnitude of the nominal *stress*.

High-Density Polyethylene (HDPE)

High-density polyethylenes (HDPEs) are thermoplastic materials that are solid in their natural state. Under extrusion conditions of heat, pressure, and mechanical shear, they soften into a highly viscous, molten mass and take the shape of the desired end product. The polymer is characterized by its opacity, chemical inertness, toughness at both low and high temperatures, and moisture barrier and electrical-insulating properties.

The term HDPE generally includes polyethylene ranging in density from about 0.94 to 0.965 g/cm³. While molecules in low-density polyethylene are branched and linked randomly, those in the higher-density polyethylene are linked in longer chains with fewer side branches, resulting in a more rigid material with greater strength, hardness, and chemical resistance and a higher softening temperature.

The physical properties of HDPE are also affected by the weight-average molecular weight (MW) of the polymer. As the MW increases, the mechanical properties also increase significantly, but the polymer becomes more difficult to process. Polymer grades with MW in the 200,000–500,000 range are considered high-performance, high-molecular-weight HDPEs (HMW HDPEs). The combination of HMW and high density provides even higher stiffness and abrasion resistance and extended product surface life in critical environmental applications. HMW resins also provide excellent environmental stress-corrosion cracking resistance. Polyethylenes with a MW 10 times that of HMW HDPE are also available. These materials, referred to as ultrahigh-molecular-weight polyethylenes (UHMWPEs), have the highest abrasion resistance and highest impact strength of any plastic.

The four major end-use markets of HMW HDPE are pipe, large-part blow molding, film, and sheet. HMW pipe is used in applications that require resistance to environmental cracking an excellent impact resistance at temperatures as low as -50°C (-60°F).

The major application areas for HMW HDPE blow-molded parts are shipping containers in sizes up to 210 L (55 gal), refuse containers, and bulk storage containers (1040 L or 275 gal). The largest of the film applications are grocery bags and garbage can liners. Typical applications for HMW sheet include truck bed liners, shipping pallets, and pond liners.

High-Energy-Rate Compacting

Compacting of a powder at a very rapid rate by the use of explosives in a closed die.

High-Energy-Rate Forging (HERF)

A closed-die hot- or cold-forging process in which the stored energy of the high-pressure gas is used to accelerate a ram to unusually high velocities in order to effect deformation of the workpiece. Ideally, the final configuration of the forging is developed in one blow or, at most, a few blows. In high-energy-rate forging, the velocity of the ram, rather than its mass, generates the major forging force. Also known as HERF processing, high-velocity forging, and high-speed forging.

High-Energy-Rate Forming

A group of forming processes that applies a high rate of strain to the material being formed through the application of high rates of energy transfer. See also *explosive forming*, *high-energy-rate forging*, and *electromagnetic forming*.

High-Energy-Rate Forming (Explosive Forming)

In a high-energy-rate forming (HERF), parts are shaped by the extremely rapid application of high pressures. Pressures as high as 13,600 MPa and speeds as high as 914 m/s may be used.

The principal advantages of HERF are as follows:

1. Parts can be formed that cannot be formed by conventional methods.
2. Exotic metals, which do not readily lend themselves to conventional forming processes, may be formed over a wide range of sizes and configurations.
3. The method is excellent for restrike operations.
4. Springback after forming is reduced to a minimum.
5. Dimensional tolerances are generally excellent.
6. Variations from part to part are held to a minimum.
7. Scrap rate is low.
8. Less equipment and fewer dies cut down on production lead time.

Explosive Forming

There are three different explosive forming techniques that have been used: free forming, bulk-head forming, and cylinder forming. Both free forming and bulkhead forming allow the workpiece to be heated before forming. Although air can be used as a coupling medium between the explosive and the workpiece, in most cases water is used. Efficiency in air is approximately 4%; in water, 33%.

Changes in mechanical properties caused by explosive forming correlate closely with those obtained in material cold-worked to the same degree.

H

In HERF of nickel alloys and the 300 series of stainless steel, strength and hardness are increased and, as expected, ductility is decreased.

Studies indicate that explosive impact hardening is useful with materials hardened by cold work, for example, austenitic stainless steel, Hadfield steel, nickel, and molybdenum. An interesting application is the possibility of restoring mechanical properties of parts that have been welded or heat-treated and thus softened.

Simple forgings can be made by explosive forming techniques. One study showed that aluminum alloys could be explosive-forged if the design had no extreme contours.

Copper has been welded to copper by the application of explosive force. The joint was metallurgical, not mechanical.

Expanding Gas

Gases generated by the burning of propellant powders in a closed container produce the pressures required to form metals. Most of the work that uses propellant powder gases as the energy source is classified as bulge-type forming.

Dynapak

Dynapak is another forming method and machine that uses a gas-powered die to form a part and the operation is under close control.

Dynapak can form low-alloy steels such as AISI 4340, austenitic steels of the 200 and 300 series, titanium, and the refractory metals, to name a few examples. It can also be used to compact powders to a density higher than normally obtained with conventional powder-metallurgy processes.

Parts have been extruded with excellent surface finish and close dimensional tolerances. Web thicknesses of 0.25 mm can be obtained and wire 0.50 mm in diameter has been extruded directly from a 25.4 mm billet.

Hot and cold forgings of various materials can be produced with zero draft angles and minimum radii. The smooth, close tolerance surfaces that are produced often minimize finish machining requirements.

Capacitor Discharge Techniques

Explosives and compressed gases are not the only means of achieving high deformation rates. In one type of device, a spark is discharged in a nonconducting liquid medium and generates a shock wave that travels at the speed of sound from the spark source to the workpiece.

This forming technique has several advantages:

1. Explosives, with their potential safety hazard, are eliminated.
2. Parts can be sized into a die by several applications of energy impulses. Since the device is electrical, components of the system do not have to be repositioned after each shot.
3. A standard machine tool, based on this principle, can be constructed for about 1/10 the cost of a conventional hydraulic press and occupy only a fraction of the floor space.

One problem encountered with capacitor discharge techniques is the containment of high voltages, because stored electrical energy increases with the square of the voltage ($E = CV^2$, where C is the

capacitance and V the voltage). There are two other problems: corona and arcing. Normal safety procedures for handling high voltage must be followed.

Magnetic Forming

Use of the pressure generated by a magnetic field permits parts to be formed in 6 s. Of this time, only 10–20 μ s may be needed for the forming operation; the balance is taken up by setup and removal of the part from the apparatus.

The many possible magnetic coil configurations permit a wide variety of forming operations from expanding to compressing to forming flat stock. Coils usually are massively supported since they must be able to withstand the high pressures generated by the magnetic field. For example, at a flux density of 300,000 Gauss, the pressure is approximately 340 MPa. At higher fields (up to 1 million Gauss), magnetic forming devices may generate pressures exceeding 3400 MPa.

The value of magnetic forming methods lies in the ability to perform quickly and economically many conventional operations such as swaging, bulging, expanding, and assembly.

High-Frequency Heating

The heating of materials by dielectric loss in a high-frequency electrostatic field. The material is exposed between electrodes and is heated quickly and uniformly by absorption of energy from the electrical field.

High-Frequency Resistance Welding

A resistance welding process that produces coalescence of metals with the heat generated from the resistance of the workpieces to a high-frequency alternating current in the 10–500 kHz range and the rapid application of an upsetting force after heating is substantially completed. The path of the current in the workpiece is controlled by use of the proximity effect (the feed current follows closely the return current conductor).

High-Impact Polystyrenes (HIPs)

High-impact polystyrenes (HIPs) are thermoplastic resins produced by dissolving polybutadiene rubber in a styrene monomer before polymerizing. Polystyrene (PS) forms the continuous phase, with the rubber phase existing as discrete particles having inclusions of PS. Different production techniques allow the rubber phase to be tailored to a wide range of properties. With advances in rubber morphology, control of molecular weight distribution, and additives, technology has enabled producers to offer a wide range of standard and specialty HIP products, which offer good dimensional stability, low-temperature impact properties, and high rigidity. Relative disadvantages of HIPs are their poor high-temperature properties and lower chemical resistance compared with most crystalline polymers.

HIPs are used in myriad applications and industries because of their ease of processing, performance, and low cost. Major industries and markets include packaging and disposables, appliances and consumer electronics, toys and recreation, buildings, and furnishings. In recent years, product development has focused on specialty products. Grades are now available that provide improved resistance to stress cracking from fats, oils, and chlorofluorocarbon blowing agents. Also available are high-gloss/high-toughness,

ignition-resistant, glass-filled (up to 40 wt.% type E glass), and very-high-impact products.

All of the conventional processing technologies for thermoplastics can be used on HIPS. These include injection molding, structural-foam molding, extrusion, thermoforming, and injection blow molding.

High Interstitial Defect

Interstitally stabilized α -phase region in titanium of substantially higher hardness than surrounding material. It arises from very high local nitrogen or oxygen concentrations that increase the β transus and produce the high-hardness, often brittle α phase. Such a defect is often accompanied by a void resulting from thermomechanical working. Also termed type I or low-density interstitial defects, although they are not necessarily low density.

Highlighting

Buffing or polishing selected areas of a complex shape to increase the luster or change the color of those areas.

Highly Deformed Layer

In tribology, a layer of severely plastically deformed material that results from the shear stresses imposed on that region during sliding contact. See also *Beilby layer* and *white layer*.

High Polymer

A macromolecular substance that, as indicated by the polymer by which it is identified, consists of molecules that are multiples of the low molecular unit and have a molecular weight of at least 20,000.

High-Pressure Laminates

Laminates molded and cured at pressures not lower than 6.9 MPa (1.0 ksi) and more commonly in the range of 8.3–13.8 MPa (1.2–2.0 ksi).

High-Pressure Molding

A plastic molding or laminating process in which the pressure used is greater than 1400 kPa (200 psi), but commonly 7000 kPa (1000 psi).

High-Pressure Spot

See *resin-starved area*.

High Pulse Current

In welding, current levels during the high pulse time that produces the high-heat level.

High Pulse Time

In welding, the duration of the high current pulse time.

High-Residual-Phosphorus Copper

Deoxidized copper with residual phosphorus present in amounts (usually 0.013%–0.04%) generally sufficient to decrease appreciably the conductivity of the copper.

High-Speed Machining

High-productivity machining processes that achieve cutting speeds in excess of 600 m/min (2,000 sfm) and up to 18,000 m/min (60,000 sfm). Such speeds result in segmented shear-localized chips rather than the continuous chip formation associated with lower-speed machining processes.

High-Speed Steels

High-speed steels are those alloy steels developed and used primarily for metal-cutting tools. They are characterized by being heat-treatable to very high hardness (usually Rockwell C64 and over) and by retaining their hardness and cutting ability at temperatures as high as 538°C, thus permitting truly high-speed machining. Above 538°C, they rapidly soften and lose cutting ability.

All high-speed steels are based on either tungsten or molybdenum (or both) as the primary heat-resisting additive, with carbon for high hardness; chromium for ease of heat treating; vanadium for grain refining and, in amounts over 1%, for abrasion resistance; and sometimes cobalt for additional hardness or resistance to heat softening.

Popular compositions of high-speed steels readily available in the United States, the most common characteristics, and recommend temperature ranges are shown in Table H.1. By far the most

TABLE H.1
High-Speed Steel

AISI Type	Austenitizing Temperature, °C	Tempering Temperature, °C	Resistance to Decarburization ^a	Characteristics
T1	1260–1288	551–580	Excellent	General purpose
T5	1274–1301	551–580	Fair	Extra heat resistance
T15	1218–1245	538–566	Good	Heaviest duty
M1	1177–1218	551–566	Poor	General purpose
M2	1190–1232	551–566	Fair	General purpose
M3	1204–1232	538–551	Fair	Heavy duty, abrasive materials
M7	1190–1227	538–566	Poor	Special applications
M10	1177–1218	538–566	Poor	General purpose
M36	1218–1245	551–580	Fair	Extra heat resistance

^a During heat treatment.

H

important of these are M1, M2, and M10. Nearly all twist drills, taps, chasers, reamers, saw blades, and high-speed steel hand tools are made from M1 or M10, whereas the more complex tools such as milling cutters, gear hobs, broaches, and form tools utilize the M2 type.

Special applications, such as machining of hard heat-treated materials, call for a more abrasion-resistant type (such as M3 or T15), and extra heavy-duty cutting involving maximum heat generation leads to the use of the high-cobalt types M36 or T5.

Properties

High-speed steel possesses the highest hardness after heat treating of any well-known ferrous alloy. The value of high-speed steel lies in its ability to retain this hardness under considerable exposure to heat and to retain a sharp cutting edge when exposed to abrasive wear.

The hardness of high-speed steel when heated-treated is usually Rockwell C64–C66, equivalent to Brinell 725–760. It is brittle at this hardness, particularly in the cobalt-bearing grades, and must be sharpened and handled carefully. This high hardness is obtained by somewhat special heat-treating techniques as compared with lower-alloyed steels. Temperatures much in excess of normal steel heat-treating temperatures are employed.

Heat Treatment

In general, for maximum hardness and heat resistance, it is necessary to heat-treat at as high a temperature as possible short of the point of initial fusion or grain growth. This would normally result in severe surface damage when done in conventional furnace atmospheres, so furnace protection by special gaseous atmospheres or by molten salt (usually BaCl_2) is required for production of quality tools.

After quenching in oil, or a salt eutectic (KCl-NaCl-BaCl_2) held at about 566°C–593°C, and air cooling to 52°C, high-speed steel is tempered in the *secondary* hardening range (523°C–566°C) to develop maximum hardness and cutting life. Such tempering is usually done two or three times successively for best results.

Occasionally, a shallow surface treatment (under 0.03 mm) is imparted by nitriding in salt, or by one of several proprietary methods, to elevate surface hardness and reduce friction. These treatments are often very useful in improving cutting life.

Use and Selection

High-speed steels are used for all types of cutting tools, particularly those powered by machines, such as drills, taps, reamers, milling cutters of all types, form cutting tools, shavers, broaches, and lathe, planar, and shaper bits. They have preference over cemented carbide when the tool is difficult to form (high-speed steel is machinable before heat treating), when subject to shock loading or vibration (high-speed steel was tough and resistant to fatigue, considering its hardness level), or when the machining problem is not particularly difficult. High-speed steel is considerably less expensive than carbides and much simpler to form into complex tools, but it does not have a high hardness, abrasion resistance, or tool life and severe high-speed cutting applications associated with cemented carbide. On the other hand, high-speed steel, with good heat resistance, consistently cuts far better than carbon steel, or one of the *fast-finishing* types.

Other uses for high-speed steel are in forming dies, drawing dies, inserted heading dies, knives, chisels, high-temperature bearings, and pump parts. In these applications, use is made of the combination of high hardness, heat resistance, and abrasion resistance rather than cutting ability.

Among the types of high-speed steel listed in Table H.1, common mass-produced tools are made from M1 or M10. These grades have the lowest cost and are easiest to machine, heat-treat, and sharpen. They also are the toughest when hard and thus withstand the abuse often given common tooling drills, taps, threading dies, etc.

More complex, expensive tools are usually made from M2 high-speed steel. It has better abrasion resistance and is easier to heat-treat in complex shapes. Most milling cutters, gear hobs, broaches, and similar multiple-point tools are in this category. M7 is also becoming popular for specialized applications.

Occasionally, extremely difficult machining operations are encountered, such as cutting plastic, synthetic wood, and paper-board products, or hardened alloy wheels. Better tool life can then be obtained by use of M3 or T15, the high-vanadium-speed steels. They are more expensive and considerably more difficult to sharpen and maintain because of resistance to grinding, but these factors are often outweighed by the superior tool life developed.

The high-cobalt high-speed steels T5 and M36 have the best heat resistance and therefore are particularly suited for tools cutting heavy castings or forgings, where cutting speeds are relatively slow, but cuts that are deep in the cutting edge get very hot. T5 and M36 are more expensive than other grades and thus have limited use, but are the most economical for some operations.

Fabrication

High-speed steels in the annealed condition are machinable by all common techniques. Their machinability rating is about 30% of Bessemer screw stock, and they must be cut slowly and carefully. The recent development of machining high-speed steels has eased this situation, but considerable care is still required.

Ordinarily, tools are machined from bar stock or forgings, either singly for complex tools or in automatic screw machines for mass production items (taps, twist drills, etc.). After finishing almost to final size, the tools are heat-treated to final hardness and then finish-ground. The manufacture of unground tools machined to final size before heat treating is growing because of improvements in heat-treating facilities and better cutting ability of a properly hardened unground surface.

After high-speed steel tools become dull, they can easily be resharpened, with some care given to selection of the proper grinding wheel and technique. They are rarely softened by annealing and re-heat-treated, since this may produce a brittle grain structure in the steel unless great care is employed. High-speed steels are never welded after hardening, and tools are seldom repaired by welding because of extreme brittleness in the weld. Often high-speed steel inserts are brazed to alloy steel bodies, or flash-welded to alloy steel shanks (heavy drills, taps, and reamers).

High-Strength Hydrogen-Resistant Alloy

NASA-23 is a hydrogen-resistant alloy that has been developed for applications in which there are requirements for high strength and high resistance to corrosion.

Adequate resistance to corrosion is necessary for the survival of alloys in hydrogen environments. Alloys for use in such

environments typically contain a minimum of 10% chromium. The unique feature of NASA-23 is that it combines high strength with resistance to corrosion and can readily be made into parts that are suitable for use in hydrogen environments.

The use of high-strength alloys that have low resistance to hydrogen results in frequent replacement of components because hydrogen severely degrades mechanical properties of these alloys. At present, coatings that serve as barriers to hydrogen/metal interactions are often applied to such alloys used in hydrogen. However, the use of coatings thus results in higher production costs. Additionally, alloys that have lower resistance to hydrogen can be used by increasing section sizes; however, this method results in an increase in component weight.

NASA-23 can be used for components that encounter temperatures up to 649°C in hydrogen environments.

Innovators of NASA-23 have carefully chosen alloying elements of iron, nickel, cobalt, chromium, niobium, titanium, and aluminum to ensure adequate precipitation hardening for strength and minimum precipitation of detrimental grain-boundary precipitates.

High-Strength Low-Alloy (HSLA) Steels

Steels designed to provide better mechanical properties and/or greater resistance to atmospheric corrosion than the conventional carbon steels. They are not considered to be alloy steels in the normal sense because they are designed to meet specific mechanical properties rather than a chemical composition (HSLA steels have yield strengths greater than 275 MPa, or 40 ksi). The chemical composition of a specific HSLA steel may vary for different product thicknesses to meet mechanical property requirements. The HSLA steels have a low carbon content (0.05% to –0.25% C) in order to produce adequate formability and weldability, and they have manganese contents of up to 2.0%. Small quantities of chromium, nickel, molybdenum, copper, nitrogen, vanadium, niobium, titanium, and zirconium are used in various combinations. The types of HSLA steels commonly used include the following:

1. Weathering steels, designed to exhibit superior atmospheric corrosion resistance.
2. Control-rolled steels, hot rolled according to a predetermined rolling schedule designed to develop a highly deformed austenite structure that will transform to a very fine equiaxed ferrite structure on cooling.
3. Pearlite-reduced steels, strengthened by very-fine-grain ferrite and precipitation hardening but with low carbon content and therefore little or no pearlite in the microstructure.
4. Microalloyed steels, with very small additions (generally <0.10% each) of such elements as niobium, vanadium, and/or titanium for refinement of grain size and/or precipitation hardening.
5. Acicular ferrite steel, very-low-carbon steels with sufficient hardenability to transform on cooling to a very fine high-strength acicular ferrite (low-carbon bainite) structure rather than the usual polygonal ferrite structure.
6. Dual-phase steels, processed to a microstructure of ferrite containing small, uniformly distributed regions of high-carbon martensite, resulting in a product with low yield strength and a high rate of work hardening, thus providing a high-strength steel with superior formability.

High-Stress Abrasion

A form of abrasion in which relatively large cutting forces are imposed on the particles or protuberances causing the abrasion and that produces significant cutting and deformation of the wearing surface. In metals, high-stress abrasion can result in significant surface strain hardening. This form of abrasion is common in mining and agricultural equipment and in highly loaded bearings where hard particles are trapped between mating surfaces. See also *low-stress abrasion*.

High-Temperature Combination

An analytical technique for determining the concentrations of carbon and sulfur in samples. The sample is burned in a graphite crucible in the presence of oxygen, which causes carbon and sulfur to leave the sample as carbon dioxide and sulfur dioxide. These gases are then detected by infrared or thermal conductive means.

High-Temperature Hydrogen Attack

A loss of strength and ductility of steel by high-temperature reaction of absorbed hydrogen with carbides in the steel resulting in decarburization and internal fissuring.

High-Temperature Materials

These are materials that serve above about 540°C. In the broad sense, high-temperature materials can be identified by the following classes of construction solids: stainless steel (limited), austenitic superalloys, refractory metals, ceramics and ceramic composites, metal-matrix composites, and graphite composites. The first three classes are well proven in industrial use, although stainless steel is served slightly above 540°C and refractory metals are usually limited to nonoxidizing atmospheric conditions. The other classes are under extensive worldwide research to establish whether they can be utilized to replace and extend the capabilities of austenitic superalloys, which are the mainstay of high-temperature service.

The most demanding applications for high-temperature materials are found in the aircraft jet engines, industrial gas turbines, and nuclear reactors. However, many furnaces, ductings, and electronic and lighting devices operate at such high temperatures. To perform successfully and economically at high temperatures, a material must have two essential characteristics: It must be strong, because increasing temperature tends to reduce strength, and it must have resistance to its environment, because oxidation and corrosion also increase with temperature.

High-temperature materials have acquired their importance because of the pressing need to provide society with energy and transportation. Machinery that produces electricity or some other form of power from a heat source operates according to a series of thermodynamic cycles, including the basic Carnot cycle and the Brayton cycle, where the efficiency of the device depends on the difference between its highest operating temperature and its lowest temperature. Thus, the greater this difference, the more efficient is the device—a result providing great impetus to the creation of materials that operate at very high temperatures.

Metallic Materials Designs

Alloys used at high temperatures in heat engines are composed of several elements. High-temperature metallurgists, using both theoretical knowledge and application of empirical experimental

H

techniques, depend upon three principal methods for developing and maintaining strength. The alloys are composed of grains of regular crystalline arrays of atoms and show usable ductility and toughness when one plane of atoms slips controllably over the next (dislocation movement); excessive dislocation movement leads to weak alloys. Thus, in terms of achieving mechanical strength, alloy design attempt to inhibit but not completely block dislocation movement.

The most common technique is solid solution strengthening. Foreign atoms of a size different from that of the parent group cause the crystal lattice to strain. This distortion impedes the tendency of the lattice to slip and thus increases strength.

A second significant mechanism is dispersion strengthening. This is the introduction into the alloy lattice of extremely hard and fine foreign phases such as carbide particles or oxide particles. Carbide dispersions can usually be created by a solid-state chemical reaction within the alloy to precipitate the particles, whereas oxide particles are best added mechanically. These hard particles impede slippage of the metal lattice simply by intercepting and locking the dislocations in place.

Still another strengthening technique is coherent-phase precipitation; a foreign phase component of similar but modestly differing crystalline structure is introduced into the alloy—always by a chemical solid-state precipitation mechanism. The phase develops significant binding strength with the mother alloy in which it resides (it is *coherent*) and, like the other mechanisms, then impedes and controls dislocation flow through the metal lattice. Coherent phase precipitation is a special case within precipitation hardening.

However, certain advances in processing have had significant effects on these classical strengthening approaches in recent years.

Metallic Materials Systems

These include superalloys, stainless steel, eutectic alloys, and intermetallic compounds.

Superalloys

High-temperature alloys also must be resistant to chemical attack by the atmosphere in which they exist, more often than not a high-speed, high-pressure gas of highly oxidizing nature. Protection from the atmosphere is achieved by causing the material to develop a tough diffusion-resistant oxide film from various elements in the alloy, or by applying a protective coating to the material.

From all this, a high degree of success has been achieved with the superalloy class of materials.

Superalloys serve under tough conditions of mechanical stressing and atmospheric attack to over 1100°C, which often is within a few hundred degrees of their melting point. These alloys are capable of supporting modern aircraft jet engines.

Undoubtedly, the most complex and sophisticated group of high-temperature alloys are the superalloys. A superalloy is defined as an alloy developed for elevated temperature service, where relatively severe mechanical stressing is encountered and high surface stability is frequently required. Superalloys, classically, are those utilized in the hottest parts of aircraft jet engines and industrial turbines; in fact, the demand of these technically sophisticated applications created the need for superalloys.

The superalloys are strengthened by all of the methods described earlier, as well as by some even more subtle ones, such as control of the boundaries between the grains of the crystalline metal by minor additives and other little understood solid-state chemical reactions.

Stainless Alloys

Stainless steels are strengthened principally by carbide precipitation and solid solution strengthening; because they cannot form

the coherent precipitate, their use is limited to about 650°C, except where strength may not be needed.

Refractory Alloys

Refractory metal alloys are based on elements that have extremely high melting points—graded in 1650°C. These elements—tungsten, tantalum, molybdenum, and niobium (columbium)—are strengthened principally by a combination of solid solution strengthening, carbide precipitation, and unique metalworking. However, they cannot be used in modern heat engines because no commercially successful method of preventing their extensive reaction with oxidizing environments for broad application has been found.

Eutectic Alloys

These metal-based systems have been under study since the late 1960s, with service applications that have not been developed. They are usually similar to or based on superalloys, but they are processed by directional solidification so that a particularly strong stable phase forms as a needlelike structure, getting unusual strength. However, they are expensive to process, and industrial use is questionable.

Intermetallic Compounds

These are metal-based systems centered on the fixed atomic compositions occurring in metallic systems of aluminum with nickel, titanium, and niobium, such as Ni₃Al, Ti₃Al, TiAl, and Nb₃Al. Intermetallic compounds are of interest because they often possess a lattice arrangement of atoms that leads to higher melting points and less ease of deformation. Some have shown ductility and toughness potential, and alloying to optimize properties is under significant study. For instance, Ti₃Al is fabricable and ductile, particularly when alloyed with niobium. None is in gas turbine service, but there is a possibility that Ti₃Al will become acceptable if the danger of titanium combustion and hydrogen embrittlement can be avoided.

Oxidation and Corrosion

In addition to possessing strength, high-temperature alloys must resist chemical attack from the environment in which they serve. Most commonly this attack is characterized by a simple oxidation of the surface. However, in machines that utilize crude or residual oils or coal or its products for fuel, natural or acquired contaminants can cause severe and complex chemical attack. Involved reaction with sulfur, sodium, potassium, vanadium, and other elements that appear in these fuels can destroy high-temperature metals rapidly—sometimes in a matter of a few hours. This is known as hot corrosion, and it is a major problem facing otherwise well-suited alloys for service in turbines operating in the combustion products of coal.

Some nuclear reactors operate above 540°C, and the working fluid is often not an oxidizing gas. For example, high-temperature gas-cooled reactors in the development stages utilize high-temperature, high-pressure helium as a working fluid. However, the helium inevitably contains very low levels of impurities—and it does not contain enough oxygen to form a protective oxide film on the metals that contain it. Impurities enter these alloys and reduce strength by precipitating excessive amounts of oxide and carbide phases and by other deleterious effects. Refractory metals, nominally of high interest here, have shown long-term degradation by carbide-related mechanisms, and so metallurgists have been working to develop resistance superalloys.

In other reactor applications such as the liquid metal fast-breeder reactor, construction metals must resist the high-temperature liquid metal to transfer heat from hot uranium-plutonium fuel.

The liquid metal is usually sodium or potassium. All classes of high-temperature alloys—stainless steels, superalloys, and refractory metals—had been under evaluation for service. As in helium gas, small amounts of impurities are the critical item. They can react with the metal at one temperature and transfer it to a component operating at a lower temperature. Stainless steels remain the prime construction materials for these breeder reactors.

The most significant problem, however, remains that of resistance to oxidation and high-temperature corrosion in present heat engines. Superalloys contain small-to-moderate amounts of highly reactive elements such as chromium and aluminum, which react easily with oxygen to form a thick tenacious semiplastic oxide surface film. This prevents further reaction of the aggressive environment with the underlying metal. This is the reason stainless steels are *stainless*—all contain a minimum of 10% chromium. Superalloys follow approximately the same rule but often also contain about 5% aluminum, which further enhances oxidation resistance. It has been found that small (<1.0%) additions of rare earth elements (such as yttrium) further improve oxidation resistance by reducing oxide spalling during the inevitable thermal cycles that gas turbines experience.

The natural protective system works well when oxidation is the only or primary type of attack. However, when the contaminants—vanadium and others—are present, they react in myriad ways in the 540°C–1100°C temperature range to destroy the protective oxide and eventually the alloy. Coating is a method used to combat this problem.

Superalloy Processes

Metallurgists have been seeking ways to increase the capability of superalloys through the development of new processes.

Oxide Dispersion Strengthening

One technique to generate improved strength is known as oxide dispersion strengthening. The objective is to distribute very fine, uniformly dispersed nonreactive oxide particles throughout the alloy. The processing usually involves starting with very fine particles of the metal itself, to which the oxide is added by a chemical or mechanical process step. The alloy is then consolidated by a mechanical pressing operation and forged into a final useful shape. Oxide dispersion strengthening materials are characterized by unusual creep resistance at very high temperatures; however, intermediate-temperature creep and all tensile properties are mediocre.

Success has been obtained in combining some of the classic strengthening factors described previously with oxide dispersion strengthening. This gives a balance of property enhancement that can be particularly useful to turbine metallurgists—good high-temperature creep strength from oxide dispersion strengthening and good intermediate-temperature strength from the other mechanisms.

Directional Solidification

A technique adaptable to investment casting is that of directional solidification, which is particularly suitable to the complex shapes of airfoil parts used in gas turbines. It has been found that by commencing the freezing of molten superalloys (held in a ceramic mold of the shape desired) at the bottom and then allowing the freezing process slowly to proceed up through the shape to be cast, the grains of the structure require a long slender shape in the direction of freezing. This significantly increases the ability of the structure to withstand mechanical load in the freezing direction and particularly increases resistance of the superalloy to a complex phenomenon involving stress and temperature cycling or temperature gradients,

known as thermal fatigue. Thermal fatigue failures commence at transverse grain boundaries by this process.

Another approach to advanced airfoil materials is to eliminate grain boundaries entirely. In directional solidification, a number of grains nucleate in the first solid to freeze, and the few with the most preferred orientation for growth choke off solidification of the others and grow along the length of the airfoil. By reducing the cross section of the first solid to form, fewer grains are nucleated. If the ceramic mold also has a short length of spiral cavity before the airfoil shape, solidification of metal through this spiral “pigtail” will allow only a single grain to grow into the airfoil section. If a particular crystal orientation with respect to the airfoil is required, a seed crystal is used instead of a pigtail. The seed placed at the bottom of the mold is long enough that the very bottom portion is not melted in the directional solidification furnace. As the mold-containing molten alloy is withdrawn, solidification occurs on the seed, with essentially the same crystal orientation as the seed. The seed can be cut from the solidified airfoil and used to seed additional airfoils. These single crystals, also known as monocrystals, allow elimination of grain-boundary strengtheners such as zirconium, carbon, boron, or hafnium. This may allow more flexibility in the remainder of the composition and higher heat treatment temperatures to optimize alloy mechanical properties and microstructure. Further freezing occurs in the 001 crystallographic direction preferred because it is in the low-elastic-modulus direction for the face-centered cubic alloys.

Powder Metallurgy

An old process, powder metallurgy (P/M), has found increased use for high-temperature superalloys and offers the possibility of added flexibility in alloy chemistry. Alloys originally developed for cast and wrought processing have been modified slightly for use as P/M materials. For large structures such as turbine disks, this has resulted in much more homogeneous chemistry and microstructure and achievement of outstanding thermal fatigue resistance. Metal flow resistance in isothermal forging is reduced because of nearly superplastic grain-boundary sliding.

Coatings

Superalloys and stainless steels must possess a balance of properties for high-temperature service. The most oxidation- and corrosion-resistant alloys do not have acceptable strength for most structural applications. Therefore, a viable solution is to utilize strong alloys for airfoil structures but then coat them to create environmental stability. This is done by adding elements such as chromium and aluminum into the surface of the alloy; these elements react with the aggressive environment to form highly protective oxides. The coating is applied by chemically reacting the turbine part with an atmosphere containing chromium or aluminum halides at very high temperature so that the active elements diffuse into the surface of the alloy to form the protective layer. Thus, ultimately, the coating layer is composed mainly of nickel from the alloy, and aluminum or chromium or both added in the coating process. Other methods developed overlayer coatings, which form not by reaction with the nickel substrate but by deposition from sources of the desired overlayer chemistry that are made by processes such as physical vapor deposition from an electron-beam-heated source, or by low-pressure plasma spraying of powders of desired coating compositions. Coatings formed by any of these methods are bonded to the substrate and the high-temperature heat treatment to cause the necessary interdiffusion. Such aluminum- and chromium-rich coatings can triple the life of industrial gas turbine parts at temperatures such as 870°C in oxidizing atmospheres.

H

Eventually, however, the coatings fail by oxidizing away or by further interdiffusion with the superalloy underneath. If a very thin layer of platinum is used, the concentration of aluminum in the surface appears to be enhanced, creating an even greater measure of protection.

Nonmetallic Materials

Considerable activity involving attempts to adapt ceramics to high-temperature applications has occurred since the mid-1960s. These are ceramics of the covalent-bonded type, such as silicon carbide and silicon nitride. Oxide ceramics, such as aluminum oxide and zirconium oxide, possess ionically bonded structures and so tend not to possess usable high-temperature creep resistance. Turbine designers and materials engineers are struggling with the problems of utilizing the covalent ceramics, because they possess great strength. It has also become apparent that these ceramics possess great oxidation and corrosion resistance—features that would be useful in turbine equipment that must handle high-temperature products of combustion from coal. Data have shown that silicon carbide and silicon nitride are attacked to only 0.05–0.08 mm in depth after 6000–8000 h exposure in corrosive atmospheres; most high-temperature metals or alloys cannot meet this performance level. However, their complete lack of ductility means that new design techniques are required to prevent early and catastrophic failure, and only very small parts have been shown to be useful so far. It is not certain that such ceramics will be usable in heat engines.

To bypass the brittleness problem, the concept of ceramic composites has emerged. In these materials, a ceramic matrix is filled with ceramic fibers, which strengthen the whole body. When subjected to a high mechanical load, the fibers pull against the matrix and slip slightly, giving the material a certain level of tolerance. This is known as fiber pullout. However, the effect is not elastic, so that it does not approach the deformation tolerance normally seen by metallic alloys that is essential for safe structures in tension.

The use of graphite and graphite/graphite compositions has also been explored and developed. Graphite has a strikingly unique combination of very low density and high elastic modulus, and it demonstrates increasing mechanical strength with increasing temperature. It is capable of mechanical service at temperatures of 2200°C or higher. However, since graphite is a form of carbon, it has virtually no oxidation resistance. Therefore, attempts to utilize graphite must involve truly extraordinary success in protecting it from oxidation. So far, protective coatings have had but limited success, and it appears that use may well be limited to rather low temperatures.

Hindered Contraction

Contraction where the shape will not permit a metal casting to contract in certain regions in keeping with the coefficient of expansion.

Hinge Stress

The tensile component of the bending stress generated on the same surface of a glass section, but not displaced from the site of a locally impinging force.

HIP

See *hot isostatic pressing*.

Histogram

A plot of frequency of occurrence versus the measured parameter.

Hob (Machine Tool)

A rotary cutting tool with its teeth arranged along a helical thread, used for generating gear teeth or other evenly spaced forms on the periphery of a cylindrical workpiece. The hob and the workpiece are rotated in timed relationship to each other while the hob is fed axially or tangentially across or radially into the workpiece. Hobs should not be confused with multiple-thread milling cutters, rack cutters, and similar tools, where the teeth are not arranged along a helical thread. See the term *gear hobbing*.

Hob (Plastic Molding)

A master model used to sink the shape of a mold into a soft steel block.

Hogging

Machining a part from bar stock, plate, or a simple forging in which much of the original stock is removed.

Hohman A-6 Wear Machine

A widely used type of wear and friction testing machine in which a rotating ring specimen is squeezed between two diametrically opposed rub blocks. This design is said to eliminate shaft flexure such as that found in other machines whose load application from the rub block to the ring is from one side only. Block geometry can be changed from flat to conforming or V-block. This type of machine is designed for use with either lubricated or unlubricated specimens.

Hold-Down Plate (Pressure Pad)

A pressurized plate designed to hold the workpiece down during a press operation. In practice, this plate often serves as a *stripper* and is also called a stripper plate.

Holding

In heat treating of metals, that portion of the thermal cycle during which the temperature of the object is maintained constant.

Holding Furnace

A furnace into which molten metal can be transferred to be held at the proper temperature until it can be used to make castings.

Holding Temperature

In heat treating of metals, the constant temperature at which the object is maintained.

Holding Time (Heat Treating)

Time for which the temperature of the heat-treated metal object is maintained constant.

Holding Time (Joining)

In brazing and soldering, the amount of time a joint is held within a specified temperature range.

Hold Time (Welding)

In resistance welding, the time during which pressure is applied to the work after the current ceases.

Hole Expansion Test

A simulative test in which a flat metal sheet specimen with a circular hole in its center is clamped between angular die plates and be formed by a punch, which expands and ultimately cracks the edge of the hole.

Hole Flanging

The forming of an integral collar around the periphery of a previously formed hole in a sheet metal part.

Hole Sawing

The use of a cylindrical saw having end teeth that cut a circular slot through the workpiece leaving a core.

Holidays

Discontinuities in a coating (such as porosity, cracks, gaps, and similar flaws) that allow areas of basis metal to be exposed to many corrosive environments that contacts the coated surface.

Hollow Milling

Using a special end-cutting mill so designed to leave a core after feeding into or through the workpiece.

Holography

A technique for recording, and later reconstructing, the amplitude and phase distributions of a wave disturbance; widely used as a method of 3D optical image formation and also with acoustical and radio waves. In optical image formation, the technique is accomplished by recording on a photographic plate the pattern of interference between coherent light reflected from the object of interest and light that comes directly from the same source or is reflected from a mirror. In acoustical holography, acoustic beams form an interference pattern of an object and a beam of light interacts with this pattern and is focused to form an optical image.

Homogeneity

The degree of uniformity of composition or properties. Contrast with *heterogeneity*.

Homogeneous

A body of material or matter, alike throughout; hence, comprised of only one chemical composition and phase, without internal boundaries.

Homogeneous Carburizing

Use of a carburizing process to convert a low-carbon ferrous alloy to one of uniform and higher carbon content throughout the section.

Homogeneous Nucleation

In the crystallization of polymers, the primary nucleated species generated by the polymer molecules.

Homogenizing

A heat-treating practice whereby a metal object is held at high temperature to eliminate or decrease chemical segregation by diffusion.

Homologous

Belonging to or consisting of a series of organic compounds differentiated by the number of methylene groups (CH₂).

Homopolymer

A polymer resulting from polymerization of a single monomer.

Honeycomb

Manufactured product of resin-impregnated sheet material (paper, fiberglass, and so on) or metal (aluminum, titanium, and corrosion-resistant alloys) foil, formed into hexagonal-shaped cells. Used as a core material in composite sandwich constructions. See also *sandwich construction*.

Honing

A low-speed finishing process used chiefly to produce uniform high-dimensional accuracy and fine finish, most often on inside cylindrical surfaces. In honing, very thin layers of stock are removed by simultaneously rotating and reciprocating a bonded abrasive stone or stick that is pressed against the surface being honed with lighter force than is typical of grinding.

Hooker Process

Extrusion of a hollow billet or cup through an annulus formed by the die aperture and the mandrel or pilot to form a tube or long cup.

Hooke's Law

A generalization applicable to all solid material, which states that stress is directly proportional to strain and is expressed as

$$\frac{\text{Stress}}{\text{Strain}} = \frac{\sigma}{\epsilon} = \text{constant} = E$$

where E is the modulus of elasticity or Young's modulus. The constant relationship between stress and strain applies only below the proportional limit. See also *modulus of elasticity*.

Hoopess Process

An electrolytic refining process for aluminum, using three liquid layers in the reduction cell.

Hopper Dryer

A combination feeding and drying device for extrusion and injection molding of thermoplastics. Hot air flows upward through the hopper containing the feed pellets. See also the term *extruder*.

H

Hopper Loader

A curved pipe through which molding plastic powders are pneumatically conveyed from shipping drums to machine hoppers.

Hoop Stress

The circumferential stress in a material of cylindrical form subjected to internal or external pressure.

Horizontal Batch Furnace

A versatile batch-type heat-treating furnace that can give light or deep case depths, and because the parts are not exposed to air, horizontal batch furnaces can give surfaces almost entirely free of oxides.

Horizontal-Position Welding

(1) Making a fillet weld on the upper side of the intersection of a vertical surface and a horizontal surface. (2) Making a horizontal groove weld on a vertical surface.

Horizontal Fixed Position (Pipe Welding)

The position of a pipe joint in which the axis of the pipe is essentially horizontal and the pipe is not rotated during welding. See also *vertical position* (pipe welding).

Horizontal Rolled Position (Pipe Welding)

The position of a pipe joint in which the axis of the pipe is essentially horizontal, and welding is carried out as the pipe is rotated about its axis. See also *vertical position* (pipe welding).

Horn

(1) In a resistance welding machine, a cylindrical arm or beam that transmits the electrode pressure and usually conducts the welding current. (2) A cone-shaped member that transmits ultrasonic energy from a transducer to a welding or machining tool. See also *ultrasonic impact grinding* and *ultrasonic welding*.

Horn Press

A mechanical metal-forming press equipped with or arranged for a cantilever block or horn that acts as the die or support for the die, used in forming, piercing, setting down, or riveting hollow cylinders and odd-shaped work.

Horn Spacing

The distance between adjacent surfaces of the horns of a resistance welding machine.

Horseshoe Thrust Bearing

A tilting-pad thrust bearing in which the top pads are omitted, making an incomplete annulus.

Hot Bed

An area adjacent to the *runout table* where hot-rolled metal is placed to cool. Sometimes called a cooling table.

Hot Box Process

In foundry practice, resin-based (furan or phenolic) binder process for molding sands similar to shell core making; cores produced with it are solid unless mandrelled out.

Hot Brake Forming

A forming process where the blank is heated up and formed in a cold tool. This is usually done very quickly, and the spring back of the material is similar to cold forming.

Hot Cathode Gun

See *thermionic cathode gun*.

Hot Chamber Machine

A *die-casting* machine in which the metal chamber under pressure is immersed in the molten metal in a furnace. The chamber is sometimes called a gooseneck, and the machine is sometimes called a gooseneck machine.

Hot-Cold Working

(1) A high-temperature thermomechanical treatment consisting of deforming a metal above its transformation temperature and cooling fast enough to preserve some or all of the deformed structure. (2) A general term synonymous with the *warm working*.

Hot Corrosion

An accelerated corrosion of metal surfaces that results from the combined effect of oxidation and reactions with sulfur compounds and other contaminants, such as chlorides, to form a molten salt on a metal surface that fluxes, destroys, or disrupts the normal protective oxide. See also *gaseous corrosion*.

Hot Cracking

(1) A crack formed in a weldment caused by the segregation at grain boundaries of low-melting constituents in the weld metal. This can result in grain-boundary tearing under thermal contraction stresses. Hot cracking can be minimized by the use of low-impurity welding materials and proper joint design. (2) A crack formed in a cast metal because of internal stress developed upon cooling following solidification. A hot crack is less open than a *hot tear* and usually exhibits less oxidation and decarburization along the fracture surface. See also *cold cracking*, *lamellar tearing*, and *stress-relief cracking*.

Hot Densification

Rapid deformation of a heated metal powder preform in a die assembly for the purpose of reducing porosity. Metal is usually deformed in the direction of the punch travel. See also *hot pressing*.

Hot-Die Forging

A hot forging process in which both the dies and the forging stock are heated; typical die temperatures are 110°C–225°C (200°F–400°F) lower than the temperature of the stock. Compare with *isothermal forging*.

Hot Dip

Covering a surface by dipping the surface to be coated into a molten bath of a coating material. See also *hot dip coating*.

Hot-Dip Coatings

A hot-dip coating is produced by immersing a base metal in a bath of the molten coating metal. Adhesion results from the tendency of the coating metal to diffuse into the base metal and form an alloy layer. Most hot-dip coatings consist of at least two distinct layers: an alloy layer and a layer of relatively pure coating metal. The alloy layer is usually a brittle intermetallic compound. Hot-dip coatings in which the alloy layer is relatively thick are not readily deformable, but modern techniques make it possible to keep the alloy layer quite thin.

Fairly thick coatings of inexpensive metals can be obtained more cheaply by hot dipping than by electroplating. Except on simple shapes, however, hot-dip coatings are nonuniform and wasteful of material. The nature of the process is such that coating metals are restricted to relatively low-melting metals, and base metals are limited to high-melting metals such as cast iron, steel, and copper.

Zinc

Properties and Uses

Hot-dipped or galvanized zinc coatings have been popular for many years for protecting ferrous products because of their ideal combination of high corrosion protection at low cost. Their corrosion protection stems from three important factors; (1) zinc has a slower rate of corrosion than iron, (2) zinc corrosion products are white and nonstaining, and (3) zinc affords electrolytic protection to iron.

The amount of protection against corrosion depends largely upon coating weight—the heavier the coating, the longer the life of the base metal. For example, a coating 0.04 mm thick is expected to have a life of 25 years in rural atmospheres, whereas a 0.88 mm coating will last 50 years. The life of zinc coatings may be 5–10 times greater in rural atmospheres than in industrial atmospheres containing sulfur and acid gases. Nevertheless, the coatings are still popular for industrial use because of their low cost.

Hot dipping is particularly valuable for zinc coating parts that cannot conveniently be made of galvanized sheet. Thus, it is quite popular for structural parts, castings, bolts, nuts, nails, poleline hardware, heater and condenser coils, windlasses, and many other products.

Application Procedures

Hot-dip zinc coatings must be applied to absolutely clean metal. Consequently, surfaces are usually cleaned in a caustic or degreasing medium and then pickled. After rinsing, parts must be fluxed to promote bonding of the zinc coating. The coating itself is applied at 449°C–460°C. A zinc-iron alloy layer is formed between the base metal and coating. Immersion time depends on the thickness of coating desired, with most coatings applied in less than 1 min.

Lead

Properties and Uses

Hot-dip lead coatings provide many important advantages over ferrous metals. They are relatively inexpensive, provide very good protection against indoor and outdoor atmospheric corrosion, and can be used in contact with many chemicals such as sulfuric, hydrochloric, hydrofluoric, phosphoric, and chromic acids. Their atmospheric corrosion resistance stems from the formation of a superficial oxide film, which is relatively impervious to corrosion.

Because of their softness, lead coatings can withstand severe deformation. Poor adhesion may be a problem since the bond is mechanical, but this problem can be minimized by adding alloying elements. Pinholes formed during application may be potential sources of corrosion but they can be eliminated by slight working or burnishing. Typical successful applications for the coatings are wire, pole line hardware, nuts, bolts, washers, tanks, barrels, cans, and miscellaneous air ducts.

Application Procedure

Because pure lead will not alloy with ferrous metals it is usually combined with an alloying agent such as tin, which alloys with iron, forming an interface between the base metal and the coating. A typical sequence of operations for coating small parts involves solvent cleaning, electrocleaning, pickling, predipping, fluxing, coating, and quenching.

Tin

Properties and Uses

Hot-dip coatings can be applied to fabricated parts made of mild and alloy steels, cast iron, and copper and copper alloys to improve appearance and corrosion resistance. Like zinc, the coatings consist of two layers—a relatively pure outer layer and an intermediate alloy layer.

An invisible surface film of stannic oxide is formed during exposure, which helps to retard, but does not completely prevent, corrosion. The coatings have good resistance to tarnishing and staining indoors, and in most rural, marine, and industrial atmospheres. They also resist foods. Corrosion resistance in all cases can be markedly improved by increasing thickness and controlling porosity. Typical applications where they can be used are milk cans, condenser and transformer cans, food and beverage containers, and various items of sanitary equipment such as cast iron mincing machines and grinders.

Application Procedure

Steel products first must be thoroughly cleaned and fluxed. They are then immersed in a preliminary tinning pot, followed by immersion in a second pot at lower temperature. Finally, the parts are withdrawn through palm oil or are dipped in a separate oil pot. Small parts are handled in one pot, centrifuged to remove excess tin, and then quenched or air-cooled. Thickness of the coatings varies from 0.3 to 0.5 mm. The aforementioned treatments are typical and variations are used for cast iron and copper and copper alloy products.

Aluminum

Aluminum hot-dip coatings (usually about 1 mm) are more expensive but much more atmospheric-resistant than zinc. The coatings are also highly heat-reflective and the aluminum-iron alloy layer is

H

highly refractory. Although these coatings seem promising for more general use in outdoor (especially industrial) atmospheres, they are currently used primarily to protect steel from high-temperature oxidation; typical applications include aircraft fire walls, toasters, automobile mufflers, and water heater casings. Hot-dip aluminum-coated (aluminized) steel sheet, strip, and wire are commercially available.

Hot Etching

Development and stabilization of the microstructure at elevated temperature in etchants or gases.

Hot Extrusion

A process whereby a heated *billet* is forced to flow through a shaped die opening. The temperature at which extrusion is performed depends on the material being extruded. Hot extrusion is used to produce long, straight metal products of constant cross section, such as bars, solid and hollow sections, tubes, wires, and strips, from materials that cannot be formed by cold extrusion.

Hot Forging

(1) A forging process in which the die and/or forging stock are heated. See also *hot-die forging* and *isothermal forging*. (2) The plastic deformation of a pressed and/or sintered powder compact in at least two directions at temperatures above the recrystallization temperature.

Hot Forming

See *hot working*.

Hot-Gas Welding

A technique for joining thermoplastic materials (usually sheet) in which the materials are softened by a jet of hot air from a welding torch and joined together at the softened points. Generally, a thin rod of the same material is used to fill and consolidate the gap.

Hot/heated Manifold Mold

A thermoplastic injection mold in which the portion of the mold (the manifold) that contains the runner system has its own heating elements, which keep the molding material in a plastic state ready for injection into the cavities, from which the manifold is insulated. See also *thermoplastic injection molding*.

Hot Isostatic Pressing

(1) A process for simultaneously heating and forming a compact in which the powder is contained in a sealed flexible sheet metal or glass enclosure and the so-contained powder is subjected to equal pressure from all directions at a temperature high enough to permit plastic deformation and sintering to take place. (2) A process that subjects a component (casting, powder forgings, etc.) to both elevated temperature and isostatic gas pressure in an autoclave. The most widely used pressurizing gas is argon. When castings are hot isostatically pressed, the simultaneous application of heat and pressure virtually eliminates internal voids and microporosity through a combination of plastic deformation, creep, and diffusion.

Hot Isostatic Pressure Welding

A diffusion welding method that produces coalescence of materials by heating and applying hot inert gas under pressure.

Hot Machining

Machining in which the workpiece shear zone is heated by auxiliary means to reduce the shear strength and increase the machinability of the material.

Hot-Melt Adhesives

Hot-melt adhesives are 100% solid thermoplastics that are applied in a molten state and form a bond after cooling to a solid state. In contrast to other adhesives, which achieve the solid state through evaporation of solvents or chemical cure, hot-melt adhesives achieve a solid state and resultant strength by cooling. In general, hot-melt adhesives are solid at temperatures below 79°C (175°F). Ideally, as the temperature is increased beyond this point, the material rapidly melts to a low-viscosity fluid that can be easily applied. Upon cooling, the adhesive sets rapidly. Because these adhesives are thermoplastics, the melting–resolidification process is repeatable with the addition and removal of the required amount of heat. Typical application temperatures of hot-melt adhesives are 150°C–290°C (300°F–550°F).

Materials that are primarily used as hot-melt adhesives include ethylene and vinyl acetate (EVA) copolymers; polyvinyl acetates (PVAs); polyethylene (PE); amorphous polypropylene; thermoplastic elastomers such as polyurethane, polyether amide, and block copolymers (e.g., styrene–butadiene–styrene, styrene–isoprene–styrene, and styrene–olefin–styrene); polyamides; and polyesters. Hot-melt adhesives can also be divided into nonpressure-sensitive and pressure-sensitive types. Nonpressure-sensitive adhesives include those for direct bonding and heat sealing. Pressure-sensitive hot-melt adhesives are tacky to the touch and can be bonded by the application of pressure alone at room temperature.

Hot-melt adhesives are used to bond all types of substrates, including metals, glass, plastics, ceramics, rubbers, and wood. Primary areas of application include packaging, bookbinding, assembly bonding (such as air filters and footwear), and industrial bonding (such as carpet tape and backings).

Hot Mill

A production line or facility for hot rolling of metals.

Hot Mill Gouges

A series of short scratches caused by slippage of one surface of a coil relative to another during hot coiling.

Hot Press Forging

Plastically deforming metals between dies in presses at temperatures high enough to avoid strain hardening.

Hot Pressing

Simultaneous heating and forming of a powder compact. See also *pressure sintering*.

Hot Pressure Welding

A solid-state welding process that produces coalescence of materials with heat and application of pressure sufficient to produce macrodeformation of the base material. Vacuum or other shielding media may be used. See also *forge welding* and *diffusion welding*. Compare with *cold welding*.

Hot Quenching

An imprecise term for various quenching procedures in which a quenching medium is maintained at a prescribed temperature above 70°C (160°F).

Hot Rod

Same as *wire rod*.

Hot-Rolled Sheet

Steel sheet reduced to the required thickness at a temperature above the point of scaling and therefore carrying hot mill oxide. The sheet may be flattened by cold rolling without appreciable reduction in thickness or by roller leveling, or both. Depending on the requirements, hot-rolled sheet can be pickled to remove hot mill oxide and is so produced when specified.

Hot-Runner Mold

A thermoplastic injection mold in which the runners are insulated from the chilled cavities and remain hot so that the center of the runner never cools during the molding cycle. Contrary to usual practice, the runners are not ejected with the molded pieces. Also called insulated-runner mold. See also *thermoplastic injection molding*.

Hot-Setting Adhesive

An adhesive that requires a temperature at or above 100°C (212°F) to set.

Hot Shortness

A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Hot shortness is caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.

Hot Size

A process where a preformed part is placed into a hot die above the annealing temperature to set the shape and remove spring back tendencies.

Hot Stamping

Engraving operation for plastics in which a design is stamped with heated metal dyes onto the face of the plastics.

Hot Strip or Pickle Line Scratch

Scratches that are superficially similar to slivers or skin laminations but originate from mechanical scoring of the strip in the hot mill, pickle line, or slitter.

Hot Top

(1) A reservoir, thermally insulated or heated, that holds molten metal on top of a mold for feeding of the ingot or casting as it contracts on solidifying, thus preventing formation of *pipe* or *voids*. (2) A refractory-lined steel or iron casting that is inserted into the tip of the mold and is supported at various heights to feed the ingot as it solidifies.

Hot Trimming

The removal of *flash* or excess metal from a hot part (such as a forging) in a trimming press.

Hot Upset Forging

A *bulk forming* process for enlarging and reshaping some of the cross-sectional area of a bar, tube, or other product form of uniform (usually round) section. It is accomplished by holding the heated forging stock between grooved dies and applying pressure to the end of the stock, in the direction of its axis, by the use of a heading tool, which spreads (upsets) the end by metal displacement. Also called hot heading or hot upsetting. See also *heading* and *upsetting*.

Hot-Wire Analyzer

An electrical atmosphere analysis device that is based on the fact that the electrical resistivity of steel is a linear function of carbon content over a range from 0.05% C to saturation. The device measures the carbon potential of furnace atmospheres (typically). This term is not to be confused with the *hot-wire test* that measures heat extraction rates.

Hot-Wire Test

Method used to test heat extraction rates of various quenchants. Faster heat-extracting quenchants will permit more electric current to pass through a standard wire because it is cooled more quickly. Compare with *hot-wire analyzer*.

Hot-Wire Welding

A variation of arc welding processes in which a filler metal wire is resistance heated as it is fed into the molten weld pool.

Hot-Worked Structure

The structure of a material worked at a temperature higher than the recrystallization temperature.

Hot Working

(1) The plastic deformation of metal at such a temperature and strain rate that recrystallization takes place simultaneously with the deformation, thus avoiding any *strain hardening*. Also referred to as hot forging and hot forming. (2) Controlled mechanical operations for

H

shaping a product at temperatures above the recrystallization temperature. Contrast with *cold working*.

Hot Zone

The part of a continuous furnace or kiln that is held at maximum temperature. Other zones are the preheat zone and cooling zone.

HSLA Steels

An interesting class of alloys known as high-strength, low-alloy (HSLA) steels has emerged in response to requirements for weight reduction of vehicles. The compositions of many commercial HSLA steels are proprietary and they are specified by mechanical properties rather than composition. A typical example, however, might contain 0.2 wt.% carbon and about 1 wt.% or less of such elements as manganese, phosphorus, silicon, chromium, nickel, or molybdenum. The high strength of HSLA steels is the result of optimal alloy selection and carefully controlled processing such as hot rolling (deformation at temperatures sufficiently elevated to allow some stress relief).

Housing Press

A type of hydraulic press in which the crown and bed are separated by uprights or spaces extending from front to back through which strain rods pass.

Hub

A *boss* that is in the center of a forging and forms a part of the body of the forging.

Hubbing

The production of forging die cavities by pressing a male master plug, known as a *hub*, into a block of metal.

Hull Cell

A special electrodeposition cell giving a range of known current densities for test work.

Humidity, Absolute

See *absolute humidity*.

Humidity Ratio

In a mixture of water vapor and air, the mass of water vapor per unit mass of dry air.

Humidity, Relative

See *relative humidity*.

Humidity, Specific

See *specific humidity*.

Humidity Test

A corrosion test involving exposure of specimens at controlled levels of humidity and temperature. Contrast with *salt fog test*.

Hybrid

A composite laminate consisting of laminae of two or more composite material systems. A combination of two or more different fibers, such as carbon and glass or carbon and aramid, in a structure. Tapes, fabrics, and other forms may be combined; usually only the fibers differ. See also *interply hybrid* and *intraply hybrid*.

Hybrid Materials

A hybrid material is a combination of two or more different material systems that results from the attachment of one material to another. For example, a hybrid composite consists of two or more types of reinforcing fibers in one or more types of matrices. By bringing together the different properties of the reinforcements, a hybrid composite can achieve improved performance with a balance in cost. Hybrid composites have been applied successfully in transportation vehicles including race cars, helicopters, powerboats, and other load-bearing components since the late 1960s. Recently, hybrid composites have been considered in infrastructure applications because of enhanced performance compared to all glass-fiber composites. It has been shown that combining carbon-fiber and glass-fiber composites will result in increased tensile and compressive stiffness, flexural stiffness and strength, fatigue performance, impact properties, and environmental resistance. The tensile failure strain of a glass-carbon hybrid composite is increased compared to all carbon-fiber composites.

Several studies on modeling of hybrid composites have demonstrated that by using an analytical model, a carbon-glass hybrid sheet molding compound (SMC) composite can have a Young's modulus up to three times as high and a density up to 15% lower than the glass SMC. For equal Young's modulus, a carbon-glass hybrid SMC with unfilled matrix costs considerably less than all carbon-fiber SMC.

Because carbon fibers are resistant to water and dilute acids, carbon-glass hybrid composites are more resistant to stress corrosion than all-glass fiber composites. The corrosion resistance of a hybrid composite is also dependent on laminate construction. Additionally, fatigue performance of hybrid composite was enhanced compared to all-glass composites.

Polymets

Polymets are a new class of hybrid materials composed of metals and polymers. Recent research has demonstrated the feasibility of extruding metal-polymer composites (polymets) of aluminum with poly(etheretherketone) and of aluminum with a liquid-crystal polymer (Al-LCP). Extrusion through either a high-shear 90° die or a converging conical die improves the properties of these aluminum polymer composites. The improvement in properties is believed to be the result of texture development, that is, the bulk and molecular orientation of the polymer in the extrusion direction. The yield strengths of these metal-polymer composites were found to be 13%–18% greater than that predicted by the rule of mixtures and their specific yield strengths 14%–21% greater than that of the aluminum control specimen.

Tensile Properties

The strength of the polymets decreases with increasing polymer content. Ductility also decreases; tensile elongation declines from 1.6% to 1.2%. Thus, the properties of the polymets are affected by the extrusion ratio; high extrusion ratios decrease the yield strength, increase ultimate tensile strength, and improve ductility of the polymets.

Continued research on Al-LCP polymets has yielded the following:

1. Formation of in-place polymer fibrils and films results from extrusion processing.
2. The ultimate tensile strength and ductility of Al-LCP aromatic polyester polymets is improved by increasing the extrusion ratio from 10.7/1 to 114/1.
3. The yield strengths of the polymets decline by increasing the extrusion ratio, but the normalized yield strengths of the polymets increase an average of 26.7%.
4. Increases in the ultimate tensile strengths and normalized yield strengths of the polymets with extrusion ratio are attributable to formation of polymer fibrils and films.
5. The energy required to produce tensile failure is significantly enhanced by increasing the extrusion ratio from 10.7/1 to 114/1.

Hydration

The chemical reaction between cement and water, forming new compounds, most of which have strength-producing properties.

Hydraulic Cement

A cement that sets and hardens by chemical interaction with water and that is capable of doing so under water.

Hydraulic Fluid

A fluid used for transmission of hydraulic pressure or action, not necessarily involving lubricant properties. Hydraulic fluids can be based on oil, water, or synthetic (fire-resistant) liquids.

Hydraulic Hammer

A gravity-drop forging hammer that uses hydraulic pressure to lift the hammer between strokes.

Hydraulic-Mechanical Press Brake

A mechanical *press brake* that uses hydraulic cylinders attached to mechanical linkages to power the ram through its working stroke.

Hydraulic Press (Metal Forming)

A press in which fluid pressure is used to actuate and control the ram. Hydraulic presses are used for both open- and closed-die forging.

Hydraulic Press (Plastic Molding)

A press in which the molding force is created by the pressure exerted by a fluid.

Hydraulic Press Brake

A *press brake* in which the ram is actuated directly by hydraulic cylinders.

Hydraulic Shear

A shear in which the crosshead is actuated by hydraulic cylinders.

Hydrazine

NH:NH is a colorless liquid boiling at 236°F (113.5°C) and freezing at 36°F (2°C). It is used as a propellant for rockets, yielding exhaust products of high temperature and low molecular weight. With a nickel catalyst it decomposes to nitrogen and hydrogen. It is a strong reducing agent and has been used in soldering fluxes, for corrosion control in boilers, in metal plating, in noble metal catalysts, and in organic syntheses. However, since it has been declared a suspected carcinogen, its use has declined. It is a starting material for antioxidants and herbicides. Reacted with citric acid, it produces the anti-tuberculosis drug *cotinazin*, which is isonicotinic acid hydrazine. It is also used as a blowing agent for foamed rubber and for the production of plastics. For industrial applications it may be used in the form of dihydrazine sulfate, a white, crystalline, water-soluble flake. Hydrazine hydrate is a colorless, water-miscible liquid. Hydrazine is made by reacting chlorine and caustic soda and treating with ammonia.

Hydride Descaling

Descaling by the action of a hydride in a fused alkali.

Hydride Phase

The phase TiH_x formed in titanium when the hydrogen content exceeds the solubility limit, generally locally due to some special circumstance.

Hydride Powder

A powder produced by removal of the hydrogen from a metal hydride.

Hydride Process

In powder metallurgy, the hydrogenation of such reactive metals as titanium and zirconium, followed by comminution of the brittle compound and vacuum treatment to remove the hydrogen from the powder.

Hydrocarbon Plastics

Plastics based on resins made by the polymerization of monomers composed of carbon and hydrogen only.

Hydrocarbons

Organic compounds of hydrogen and oxygen. Most organic compounds are hydrocarbons. Aliphatic hydrocarbons are straight-chained structures. Aromatic hydrocarbons are ringed structures

H

based on the benzene ring. Methyl alcohol and trichloroethylene are among the aliphatic; benzene, xylene, and toluene are among the aromatic.

Hydrochloric Acid

Hydrochloric acid (HCl) is soluble in water and is a strong mineral acid made by the action of sulfuric acid on common salt, or as a by-product of the chlorination of hydrocarbons such as benzene.

Uses

HCl is used to some extent in pickling of metal prior to porcelain enameling. Pickling solutions generally contain 5%–10% HCl and should be contained in steel tanks lined with acid-proof brick. Rubber-lined tanks may be used for small jobs. Pickling temperatures range from room temperature up to -93°C ; pickling times range from 2 to 15 min, depending on metal condition, acid strength, and temperature.

HCl will pickle faster than sulfuric acid. Also, the metal surface will be cleaner because the iron salts formed during pickling rinse off more readily. The danger of overpickling is greatly reduced by the use of HCl, because chlorine radical does not promote defects as readily as does the sulfate radical of H_2SO_4 . HCl requires no steam for heating. Metal sheet should not be immersed in HCl longer than 12–15 min.

Also called *muriatic acid* and originally called *spirits of salt*. An inorganic acid used for pickling and cleaning metal parts; producing glues and gelatin from bones; manufacturing chlorine, chlorine dioxide, pharmaceuticals, dyes, and pyrotechnics; recovering zinc from galvanized iron scrap; making high-fructose corn syrup; tanning, etching, and reclaiming rubber; and treating oils and fats. It is a water solution of hydrogen chloride and is a colorless or yellowish fuming liquid with pungent, poisonous fumes. Fuming HCl has a specific gravity of 1.194 and contains about 37% hydrogen chloride gas. Reagent-grade HCl is usually of this high strength and is clear and colorless, unlike the impure fuming variety. HCl is shipped in class carboys. Anhydrous hydrogen chloride gas is also marketed in steel cylinders for use as a catalyst. The acid known as “aqua regia,” used for dissolving or testing gold and platinum, is a mixture of 3 parts HCl and 1 nitric acid. It is a yellowish liquid with suffocating fumes.

Hydrocyanic Acid

Also called *prussic acid*, *formonitrile*, and *hydrogen cyanide*. A colorless, highly poisonous gas of composition HCN. The specific gravity is 0.697, the liquefying point is 79°F (26°C), and it is soluble in water and in alcohol. It is usually marketed in water solutions of 2%–10%. It is used for the production of acrylonitrile and adiponitrile and for making sodium cyanide. It is also employed as a disinfectant and fumigant, as a military poison gas, and in mining and metallurgy in the cyanide process. It is so poisonous that death may result within a few seconds after it is taken into the body. It was used as a poison by the Egyptians and Romans, who obtained it by crushing and moistening peach kernels. It is produced synthetically from natural gas. The French war gas known as *vincennite* was hydrocyanic acid mixed with stannic chloride. *Manganite* was a mixture with arsenic trichloride. HCN discoids are cellulose disks impregnated with 98% hydrocyanic acid, used for fumigating in closed warehouses.

Hydrodynamic Lubrication

A system of lubrication in which the shape and relative motion of the sliding surfaces cause the formation of a fluid film that has sufficient

pressure to separate the surfaces. See also *elastohydrodynamic lubrication* and *gas lubrication*.

Hydrodynamic Seal

A seal that has special geometric features on one of the mating faces. These features are designed to produce interfacial lift, which arises solely from the relative motion between the stationary and rotating portions of the seal.

Hydrofluoric Acid

A water solution of *hydrogen fluoride*, HF. It is a colorless, fuming liquid, highly corrosive and caustic. It dissolves most metals, except gold and platinum, and glass, stoneware, and organic material. The choking fumes are highly injurious. It is widely used in the chemical industry, for etching glass, and for cleaning metals. In cleaning iron castings, it dissolves the sand from the castings. The specific gravity of the gas is 0.99, and the boiling point is 67°F (19.5°C). Hydrofluoric acid is made by treating calcium fluoride or fluorspar with sulfuric acid. It is marketed in solution strengths of 30%, 52%, 60%, and 80%. The anhydrous material, HF, is used as an alkylation catalyst. *Hydrobromic acid*, HBr, is a strong acid that reacts with organic bases to form bromides that are generally more reactive than chlorides. The technical 48% grade has a specific gravity of 1.488.

Hydrogen

A colorless, odorless, tasteless elementary gas, with an atomic weight of 1.008, hydrogen is the lightest known substance. The specific gravity is 0.0695, and its density ratio in relation to air is 1:14.38. It is liquefied by cooling under pressure, and its boiling point at atmospheric pressure is -252.7°C . Its light weight makes it useful for filling balloons, but because of its flammable nature, it is normally used only for signal balloons, for which use the hydrogen is produced easily and quickly from hydrides. Hydrogen (H_2) produces high heat and is used for welding and cutting torches. For this purpose it is used in atomic form rather than the usual H_2 molecular form. Its high thrust value makes it an important rocket fuel. It is also used for the hydrogenation of oil and coal, for the production of ammonia and many other chemicals, and for water gas, a fuel mixture of hydrogen and carbon monoxide made by passing steam through hot coke.

Hydrogen is so easily obtained in quantity by the disassociation of water and as a by-product in the production of alkalies by the electrolysis of brine solutions that it appears as a superabundant material, but its occurrence in nature is much less than that of many of the other elements. It occurs in the atmosphere to the extent of only about 0.01% and in the Earth's crust to the extent of about 0.2%, or about half that of the metal titanium. However, it constitutes about 1/9 of all water, from which it is easily obtained by high heat or by electrolysis.

Hydrogen has three isotopes. Hydrogen-2, called deuterium, occurs naturally in ordinary hydrogen-1, called protium, to the extent of one part in about 5000. Deuterium has one proton and one neutron in the nucleus, with one orbital electron revolving around. A gamma ray will split off the neutron, leaving a single electron revolving around a single proton. Deuterium is also called double-weight hydrogen. Deuterium oxide is known as heavy water. The formula is H_2O , but with the double-weight hydrogen, the molecular weight is 20 instead of the 18 for ordinary water.

Heavy water is used for shielding atomic reactors because it is more effective than graphite in slowing down fast neutrons. Hydrogen-3 is triple-weight hydrogen and is called tritium. It has two neutrons and one proton in the nucleus and is radioactive. It is a by-product of nuclear fission reactors, and most commercial production is from this source. It is a beta emitter with little harmful secondary ray emission, which makes it useful and self-luminous phosphorus. It is a solid at very low temperatures. Liquid hydrogen for rocket fuel use is made from ordinary hydrogen.

Hydrides are metals that contain hydrogen in a reduced state and as a solid solution in their lattice. Titanium hydride and zirconium hydride have catalytic activity. Lanthanum and cerium react with hydrogen at room temperature forming hydrides and are used for storing hydrogen. Sodium borohydride is used commercially as a reducing agent, for removing trace impurities from organic chemicals, in the synthesis of pharmaceuticals, for wood-pulp bleaching, for brightening clay, and for recovering trace metals in effluents. Silicate hydride, also known as silane, is a gas used for manufacturing ultrapure silicon for fabrication into semiconductors. *Gelled hydrogen* for rocket fuel is liquid hydrogen thickened with silica powder.

Hydrogen-Assisted Cracking (HAC)

See *hydrogen embrittlement*.

Hydrogen-Assisted Stress-Corrosion Cracking (HSCC)

See *hydrogen embrittlement*.

Hydrogen Blistering

The formation of blisters on or below a metal surface from excessive internal hydrogen pressure. Hydrogen may be formed during cleaning, plating, or corrosion.

Hydrogen Brazing

A term sometimes used to denote brazing in a hydrogen-containing atmosphere, usually in a furnace; use of the appropriate process name is preferred.

Hydrogen Damage

A general term for the embrittlement, cracking, blistering, and hydride formation that can occur when hydrogen is present in some metals.

Hydrogen Electrode

A reference electrode against which other materials are compared to determine their electrode potential. See *electrochemistry*.

Hydrogen Embrittlement

A process resulting in a decrease of the *toughness* or *ductility* of a metal due to the presence of atomic hydrogen. Hydrogen embrittlement has been recognized classically as being of two types.

The first, known as internal hydrogen embrittlement, occurs when the hydrogen enters molten metal that becomes supersaturated with hydrogen immediately after solidification. The second type, environmental hydrogen embrittlement, results from hydrogen being absorbed by solid metals. This can occur during elevated temperature thermal treatments and in service during electroplating, contact with maintenance chemicals, corrosion reactions, cathodic protection, and operating in high-pressure hydrogen. In the absence of residual stress of external loading, environmental hydrogen embrittlement is manifested in various forms, such as blistering, internal cracking, hydride formation, and reduced ductility. With a tensile stress or stress-intensity factor exceeding a specific threshold, the atomic hydrogen interacts with the metal to induce subcritical crack growth leading to fracture. In the absence of a corrosion reaction (polarized cathodically), the usual term used is hydrogen-assisted cracking (HAC) or hydrogen stress cracking (HSC). In the presence of active corrosion, usually as Spitz or crevices (polarized anodically), the cracking is generally called *stress-corrosion cracking* (SCC), which should more properly be called hydrogen-assisted stress-corrosion cracking (HSCC). Thus, HSC and electrochemically anodic SCC can operate separately or in combination (HSCC). In some metals, such as high-strength steels, the mechanism is believed to be all, or nearly all, HSC. The participating mechanism of HSC is not always recognized and may be evaluated under the generic heading of SCC.

Even when hydrogen produces no readily observable crack, it may reduce the ductility of certain steels—termed hydrogen embrittlement—and it can lead to delayed fracture, also termed sustained load failure, under an otherwise acceptable steady load. Steel boiler tubes charged with hydrogen as a result of severe water-side corrosion suffer a reaction between a carbon of the steel and the hydrogen to form methane, CH_4 . This causes local decarbonization and internal cracking leading to significant weakening. The resultant failure is of low ductility leading again to the term hydrogen embrittlement, although this particular usage is not usually recognized outside the power industry. Tough pitch copper, that is, copper containing oxygen as finally distributed copper oxide particles, is damaged if exposed to hydrogen-rich atmospheres during heat treatment, welding, brazing, or service. The hydrogen reacts with the oxide to form water that causes internal fissuring with serious effects on the strength and toughness of the material. The term gassing is specific to this form of attack although the terms hydrogen embrittlement and hydrogen damage are occasionally used. Some titanium alloys suffer a considerable reduction of impact strength when charged with hydrogen due to the formation of hydride platelets that impede slip. See also *fisheyes*.

Hydrogen Fluoride

Hydrogen fluoride is the hydride of fluorine and the first member of the family of halogen acids. Anhydrous hydrogen fluoride is a mobile, colorless liquid that fumes strongly in air. It has the empirical formula HF , melts at -83°C , and boils at 19.8°C . The vapor is highly aggregated, and gaseous hydrogen fluoride deviates from perfect gas behavior to a greater extent than any other gaseous substance known.

Hydrogen fluoride is prepared on the large industrial scale by treating fluor spar (calcium fluoride, CaF_2) with concentrated sulfuric acid. The crude product is purified by fractional distillation to yield a product containing more than 99.5% hydrogen fluoride.

H

Properties

Anhydrous hydrogen fluoride is an extremely powerful acid, exceeded in this respect only by 100% sulfuric acid. Like water, hydrogen fluoride is a liquid of high dielectric constant that undergoes self-ionization and forms conducting solutions with many solutes. Because anhydrous hydrogen fluoride is a superacid, many organic solutes dissolve in it to form stable carbonium ions. Alkali metal fluorides and silver fluoride dissolve readily in hydrogen fluoride to form conducting solutions. The alkali metal fluorides are bases in the hydrogen fluoride systems and correspond to solutions of alkali metal hydroxides in water.

Conversely, antimony pentafluoride and boron trifluoride act as acids in hydrogen fluoride and accentuate the already strong acid properties of the solvent.

Uses

Hydrogen fluoride is a widely used industrial chemical. It was formally used in the petroleum refining industry for the isomerization of aliphatic hydrocarbons to form more desirable automotive fuels, but this application has been superseded by other methods. The largest industrial use of hydrogen fluoride is in making fluorine-containing refrigerants (Freons, Genetrons).

Another important use of hydrogen fluoride is in the preparation of organic fluorocarbon compounds by the Simons electrochemical process. In this procedure, an organic compound is dissolved in hydrogen fluoride, and an electric current is passed through the solution, whereupon the hydrogen atoms in the organic solute are replaced by fluorine. Hydrogen fluoride is employed in the electrochemical preparation of fluorine and for the preparation of inorganic fluorides. Thus, hydrogen fluoride is used for the conversion of uranium dioxide to uranium tetrafluoride and intermediate in the preparation of uranium metal and uranium hexafluoride. With the great increase in nuclear energy-produced electricity, this represents an important use of hydrogen fluoride.

Both hydrogen fluoride and hydrofluoric acid cause unusually severe burns; appropriate precautions must be taken to prevent any contact of the skin or eyes with either the liquid or the vapor.

Hydrogen-Induced Cracking (HIC)

Same as *hydrogen embrittlement*.

Hydrogen-Induced Delayed Cracking

A term sometimes used to identify a form of *hydrogen embrittlement* in which a metal appears to fracture spontaneously under a steady stress less than the *yield stress*. There is usually a delay between the application of stress (or exposure of the stressed metal to hydrogen) and the onset of cracking. Also referred to as static fatigue.

Hydrogen Loss

The loss in weight of metal powder of a compact caused by heating a representative sample according to a specified procedure in a purified hydrogen atmosphere. Broadly, a measure of the oxygen content of the sample when applied to materials containing only such oxides as are reducible with hydrogen and no hydride-forming element.

Hydrogen Overvoltage

In electroplating, *overvoltage* associated with the liberation of hydrogen gas.

Hydrogen Peroxide

A liquid that readily yields oxygen for bleaching and oxidizing purposes. The C. P. grade of hydrogen peroxide is a colorless liquid with 90% H_2O_2 and 10 water. The specific gravity is 1.39. It contains 42% active oxygen by weight, and 1 volume yields 410 volumes of oxygen gas. Grades for oxidation and bleaching contain 27.5% and 35% H_2O_2 . It is also used as an oxidizer for liquid fuels. A variety of chemicals are used for providing oxygen for chemical reactions. These are known as *oxidizers* or *oxidants*, and they may be peroxides or superoxides, which are compounds with the oxygen atoms singly linked. They break down into pure oxygen and a more stable reduced oxide. Sodium peroxide is used in submarines to absorb carbon dioxide and water vapor and to give off oxygen to restore the air. To provide oxygen and rockets and missiles, *lithium nitrate*, LiNO_3 , with 70% available oxygen, and *lithium perchlorate*, $\text{LiClO}_4 \cdot 3\text{H}_2\text{O}$, with 60% available oxygen, are used. Another rocket fuel oxidizer that is liquid under moderate pressure and is easily stored is *perchloryl fluoride*, ClO_3F , normally boiling at -52°F (-47°C).

Liquid air was first used in the first V-2 rockets, with alcohol, potassium permanganate, and hydrogen peroxide. Liquid air is used in the chemical industry and for cold-treating. It is atmospheric air liquefied under pressure, and it contains more than 20% free oxygen.

Oxidizers and *reducers*, or *reductants*, are used in solutions for water disinfection, bleaching, cyanide destruction, chromium reduction, and metal etching. Common oxidizers include *chlorine*, *bromine*, *ozone*, *sodium hypochlorite*, and *hydrogen peroxide*. Well-known reductants include *sodium bisulfate*, or *sodium metabisulfate*, and *sulfur dioxide*. Ozone is about twice as effective as bromine. Because of environmental concerns in recent years, hydrogen peroxide has displaced chlorine in various water treatment and pollution-control applications.

Hydrogen-Reduced Powder

Metal powder produced by hydrogen reduction of a compound.

Hydrogen Stress Cracking (HSC)

See *hydrogen embrittlement*.

Hydrolysis

- (1) Decomposition or alteration of a chemical substance by water.
- (2) In aqueous solutions of electrolytes, the reactions of cations with water to produce a weak base or of anions to produce a weak acid.

Hydrolytic Stability

The ability of an organic or polymeric material to withstand an irreversible change of state when exposed to elevated temperature and humidity.

Hydromatic Welding

See preferred term *pressure-controlled welding*.

Hydromechanical Press

A press in which forces are created partly by a mechanical system and partly by a hydraulic system.

Hydrometallurgy

Industrial *winning* or *refining* of metals using water or an aqueous solution.

Hydrometer

Instruments for measuring the density of liquid.

Hydrophilic

Having an affinity for water; easily wetted by water. Contrast with *hydrophobic*.

Hydrophobic

Lacking an affinity for, repelling, or failing to absorb water; poorly wetted by water. Contrast with *hydrophilic*.

Hydrostatic

Acting equally in all directions. In hydrostatic tension, the three principal stresses are equal.

Hydrostatic Bearing

A bearing in which the solid bodies are separated and supported by hydrostatic pressure, applied by an external source, to a compressible or incompressible fluid interposed between those bodies.

Hydrostatic Compaction

Pressing processes in which powders intended for sintering are enclosed in a flexible bag or similar container and subjected to a high-pressure environment, usually hydraulic. This allows the use of a higher but more even pressure than conventional pressing and reduces wear of the equipment. See *hydrostatic pressing*.

Hydrostatic Extrusion

A method of extruding a *billet* through a die by pressurized fluid instead of the ram used in conventional *extrusion*.

Hydrostatic Lubrication

A system of lubrication in which the lubricant is supplied under sufficient external pressure to separate the opposing surfaces by a fluid film. See also *pressurized gas lubrication*.

Hydrostatic Modulus

See *bulk modulus of elasticity*.

Hydrostatic Mold

In powder metallurgy, a sealed flexible mold made of rubber, a polymer, or pliable sheet made from a low-melting metal such as aluminum.

Hydrostatic Pressing

A special case of isostatic pressing that uses a liquid such as water or oil as a pressure transducing medium and is therefore limited to near room temperature operation.

Hydrostatic Seal

A seal incorporating features that maintain an interfacial film thickness by means of pressure. The pressure is provided either by an external source or by the pressure differential across the seal. The interfacial pressure profile of a seal face is normally speed-dependent; the interfacial pressure profile of the hydrostatic seal is not speed-dependent.

Hydrostatic Tension

Three equal and mutually perpendicular tensile stresses.

Hydroxyl Group

A chemical group consisting of one hydrogen atom and one oxygen atom. The OH portion of a compound occurring in solution as the OH⁻ ion.

Hygroscopic

(1) Capable of attracting, absorbing, and retaining atmospheric moisture. (2) Possessing a marked ability to accelerate the condensation of water vapor; applied to condensation nuclei composed of salts that yield aqueous solutions of a very-low-equilibrium vapor pressure compared with that of pure water at the same temperature. (3) Pertaining to a substance whose physical characteristics are appreciably altered by effects of water vapor. (4) Pertaining to water absorbed by dry soil minerals from the atmosphere; the amounts depend on the physicochemical character of the surfaces, and increase with rising relative humidity.

Hygrothermal Effect

Change in properties of the material (particularly plastics) due to moisture absorption and temperature change.

Hypereutectic Alloy

In an alloy system exhibiting a *eutectic*, any alloy whose composition has an excess of alloying element compared with the eutectic composition and whose equilibrium microstructure contains more eutectic structure.

Hypereutectoid Alloy

In an alloy system exhibiting a *eutectoid*, any alloy whose composition has an excess of alloying element compared with the eutectoid composition and whose equilibrium microstructure contains some eutectoid structure.

Hypoeutectic Alloy

In an alloy system exhibiting a *eutectic*, any alloy whose composition has an excess of base metal compared with the eutectic

H

composition and whose equilibrium microstructure contains some eutectic structure.

Hypoeutectoid Alloy

In an alloy system exhibiting a *eutectoid*, any alloy whose composition has an excess of base metal compared with the eutectoid composition and whose equilibrium microstructure contains some eutectoid structure.

Hypoid Bevel Gear

A gear that transmits rotary motion between parallel shafts that are usually at 90° to each other. In a hypoid gear set, the axis of the pinion is offset somewhat from the axis of the gear.

Hypoid Gear Lubricant (Hypoid Oil)

A gear lubricant with extreme-pressure characteristics used in hypoid gears.

Hysteresis (Magnetic)

The lag or delay in the change of one variable as another related variable changes. For example, magnetic induction lags behind the

change in the magnetizing force. The hysteresis loss is the loss arising from a single cycle of the hysteresis loop.

Hysteresis (Mechanical)

The phenomenon of permanently absorbed or lost energy that occurs during any cycle of loading or unloading when a material is subjected to repeated loading.

Hysteresis Loop (Magnetic)

A closed curve that characterizes the magnetization/demagnetization characteristics as a function of the applied magnetic field for magnetic materials.

Hysteresis Loop (Mechanical)

In dynamic mechanical measurement, the closed curve representing successive stress–strain status of a material during a deformation cycle.

Hz

Hertz.

IACS

International annealed copper standard; a standard reference used in reporting electrical conductivity. The conductivity of a material, in %IACS, is equal to 1724.1 divided by the electrical resistivity of the material in $\text{n}\Omega \cdot \text{m}$.

Iceland Spar

A transparent form of calcite.

I.D.

Internal diameter.

Ideal Crack

A simplified model of a crack used in elastic stress analysis. In a stress-free body, the crack has two smooth surfaces that are coincident and join within the body along a smooth curve called the crack front; in 2D representations, the crack front is called the crack tip.

Ideal-Crack-Tip Stress Field

The singular stress field, infinitesimally close to the crack front, that results from the dominant influence of an ideal crack in an elastic body that is the form. In a linear-elastic homogeneous body, the significant stress components vary inversely as the square root of the distance from the crack tip. In a linear-elastic body, the crack-tip stress field can be regarded as the superposition of three component stress fields called *modes*.

Ideal Critical Diameter (D_1)

Under an ideal quench condition, the bar diameter that has 50% martensite at the center of the bar when the surface is cooled at an infinitely rapid rate (i.e., when $H = \text{infinity}$, where H is the quench severity factor or *Grossman number*).

Identification Etching

Etching to expose particular microconstituents; all others remain unaffected.

Idiomorphic Crystal

An individual crystal that has grown without restraint so that the habit planes are clearly developed. Crystals having a shape corresponding to their crystal lattice. They occur when there is no external constraint to their growth. Compare with *allotriomorphic crystal*.

Ignition Loss

(1) The difference in weight before and after burning. (2) The burning off of *binder* or *size*.

Ignition Temperature

The temperature at which combustion can commence. See also *gas cutting*.

Ihrigizing

A process for forming a hard corrosion-resistant silicon coating on steel by heating at high temperature in a silicon tetrachloride vapor.

Illumination

The luminous flux density incident on a surface; the ratio of flux to area of illuminated surface.

Image

A representation of an object produced by radiation, usually with a lens or mirror system.

Image Analysis

Measurement of the size, shape, and distributional parameters of microstructural features by electronic scanning methods, usually automatic or semiautomatic. Image analysis data output can provide individual measurements on each separate feature (feature specific) or field totals for each measured parameter (field specific).

Image Contrast

A measure of the degree of detectable difference in intensity within an image.

Image Rotation

In electron optics, the angular shift of the electron image of an object about the optic axis induced by the tangential component of force exerted on the electrons perpendicular to the direction of motion in the field of a magnetic lens.

Immersed-Electrode Furnace

A furnace used for liquid carburizing of parts by heating molten salt baths with the use of electrodes immersed in the liquid. See also *submerged-electrode furnace*.

Immersion Cleaning

Cleaning in which the work is immersed in a liquid solution.

Immersion and Chemical Coatings

Immersion coatings are applied without electricity by immersing parts in a chemical solution or bath containing the metal to be deposited. Deposition can take place either by displacement, when the metal in solution displaces the base metal, or by reduction, where the base metal does not enter into the reaction.

Although many metals can be deposited in immersion baths, comparatively few have proved acceptable for decorative or functional applications. These are nickel, tin, copper, gold, and silver.

Electroless Nickel

Properties

Electroless nickel is generally more expensive than electroplated nickel. For this reason, it is used primarily for its functional properties; although it is very smooth, bright deposit can be obtained on buffed ferrous and nonferrous metals.

Because of its amorphous structure and phosphorus content (8%–10%), the coatings are said to have better corrosion resistance than electrolytic or wrought nickel. Hardness of the coatings is relatively high—about 50 R_c —and can be raised to 64 R_c by heat treatment. Thickness of the coatings ranges from 1 to 5 mils, depending on end use.

Applications

The most important uses for electroless nickel are to protect parts from corrosion and to prevent product contamination. The coatings are widely used on tank-car interiors to protect caustic soda, ethylene oxide, tetraethyl lead, tall oil, and many other liquids from contamination. Other similar applications include oil refinery air compressors, missile fuel for plates, gas storage bottles for liquid, and pumps for petroleum and related products.

The hardness of the coatings is particularly valuable in increasing the life of rotating and reciprocating surfaces in gas compressors, pumps, hydraulic cylinders, sheaves, and armatures. The coatings are also used on aluminum electronic devices to facilitate soldering, on stainless steel to facilitate brazing, on moving metal parts to prevent galling, and on stainless steel equipment to prevent stress corrosion cracking.

Tin

Properties

Tin immersion coatings are especially noted for their low cost, bright appearance, good frictional properties, and ease of application to many common metals such as copper, brass, bronze, aluminum, and steel. However, their corrosion resistance is only fair.

As with some other immersion coatings, plating usually stops when the base metal is completely covered. Thus, thickness for common decorative uses is limited to about 0.015 mils. However, thicknesses up to 2 mils for heavy-duty applications have been produced by placing the base metal in contact with a dissimilar metal, thereby generating current and promoting additional plating.

Applications

Tin immersion coatings are popular for decorative finishing of small parts such as safety pins, thimbles, and buckles. They are also applied

to copper tubing to prevent discoloration from water and to aluminum engine pistons to provide lubrication during break-in periods.

Copper

Properties

The most important characteristics of copper immersion coatings are their high electrical conductivity, good lubrication properties, and unique appearance. In addition to steel, they can be applied to brass and aluminum and to printed circuit boards. Usual thickness range is 0.1–1 mils.

Applications

Because of their conductivity, copper immersion coatings have proved particularly useful for printed circuits. They are not especially noted for their decorative appeal, but can be used in applications where a particular appearance is required, for example, inexpensive, decorative hardware such as casket parts. Because of their good lubrication properties, they can also be used on steel wire in die-forming operations.

Gold

Properties

Gold immersion coatings are relatively inexpensive because of their extreme thinness—about 0.001 mil. The coatings have good electrical conductivity and emissivity characteristics and a bright, attractive appearance. As deposited, they are not especially resistant to discoloration and abrasion; however, they can be protected with a clear lacquer finish. They are used on a wide variety of ferrous and nonferrous metals and on copper printed circuit boards.

Applications

Because of their good appearance, gold immersion coatings are principally used on costume jewelry, trophies, auto trim, and inexpensive novelties. Their conductivity and solderability are used to advantage in electrical applications such as printed circuits, transistors, and connectors. Also, the unique emissivity properties of the coatings have proved useful in missile applications.

Silver

Properties

Like gold, silver immersion coatings are relatively inexpensive because of their extreme thinness. The coatings have a bright, attractive appearance when first deposited. Their resistance to tarnishing and abuse is poor; however, they can be protected somewhat with a clear lacquer coating.

Silver immersion coatings can be applied to most base metals except lead, zinc, aluminum, and very active metals. They perform best on copper, nickel, and steel. Usual thickness is about 0.001 mil, but 0.03 mil can be deposited in some cases.

Applications

Because of their poor durability, silver immersion coatings are not too popular; the only applications are cheap decorative products, minor electronic parts, and maintenance plating.

Immersion Etching

Method in which a microsection is dipped face up into etching solution and is moved around during etching. This is the most common etching method.

Immersion Lens

See *immersion objective*.

Immersion Objective

In optical microscopy, an objective in which a medium of high refractive index is used in the object space to increase the numerical aperture and therefore the resolving power of the lens.

Immersion Objective (Electron Optics)

A lens system in which the object space is at a potential or in a medium of index of refraction different from that of the image space.

Immersion Oil

An oil that is interposed between the specimen and the objective lens of a microscope. It has a high refractive index compared with air and hence improves the resolving power.

Immersion Plating

Depositing a metallic coating on a metal immersed in a liquid solution, without the aid of an external electric current. Also called *dip plating*.

Immiscible

(1) Of two phases, the inability to dissolve in one another to form a single solution; mutually insoluble. (2) With respect to two or more fluids, not mutually soluble; incapable of attaining homogeneity.

Immunity

A state of resistance to corrosion or anodic dissolution of a metal caused by thermodynamic stability of the metal.

Impact Bruise

See *percussion cone*.

Impact Energy

The amount of energy, usually given in joules or foot-pound force, required to fracture a material, usually measured by means of an *Izod test* or *Charpy test*. The type of specimen and test conditions affects the values and therefore should be specified.

Impact Extrusions

Impact extrusion consists of subjecting metallic materials to very high pressures at room temperature. Under these pressures,

the metals become “plastic” and assume predetermined shapes. Whereas in coining this process takes place within a closed die, typical impact extrusions allow a portion of the metal to be “squirted” or “squeezed” out of the die cavity, thereby forming an integral part of the desired shape.

From a practical point of view, impact extrusion of suitable parts may result in substantially lower unit manufacturing cost because it permits

1. High production rates
2. Substantial material savings (up to 75%)
3. Little or no machining
4. Low initial tool costs and long tool life
5. Bright and smooth surface finish ready for decorating

There are two types. Impact extrusion of the slug takes place between punch and die. Under pressure, the metal may be forced to flow counter to the direction of punch travel (backward extrusion) or in the direction of punch travel (forward extrusion). Frequently, parts require a combination of both types.

Starting Material

The raw material for the process is usually referred to as a slug. Slugs may be blanked from sheet or plate, sawed from bar stock, or cast. The cross section of a slug—round, oval, square, or rectangular—fits into the die bottom; its height is determined by the volume of metal required to produce the part.

Equipment Selection

The pressures necessary for impact extrusion are available on mechanical or hydraulic presses. Mechanical presses are usually preferred when higher production rates are required. Both toggle and crank presses are used—depending on load and performance characteristics required. Hydraulic presses have primarily been used for forward extrusions requiring particularly high pressures and heavy cross sections. Factors bearing on the selection of equipment for impact extrusion are dimensional characteristics of the part to be produced, tonnage, and speed.

Dimensional characteristics of the part (diameter, height, etc.) determine die size of the press and length of stroke required.

Tonnage required for metal flow must be carefully determined in advance. It is predicated on the relative plastic deformation required for the part, that is, the ratio of the cross-sectional area of the extruded part to the area of the slug. Maximum limits of plastic deformation vary from 90%–95% for 99.5% aluminum, lead, and tin to 70%–80% for mild steel and brasses.

Design Criteria

Impact extrusion should be specified by the designer primarily for the following:

1. Parts that are essentially hollow shells consisting of a wall and a bottom or partial bottom section. While in drawing the ratio between height and bottom diameter is limited to approximately 2 to 3:1, it is possible to impact-extrude (backward) up to 8:1. Forward extrusions many times as long as the diameter have also been made.
2. Parts with straight, no-draft walls.
3. Parts requiring high-strength characteristics.

4. Parts with longitudinal ribs, flutes, splines, etc., or with bosses, cavities, etc., in the bottom section.
5. Parts made in large quantities calling for low unit costs.

Applications

It is significant for this process that the flow of metal takes place primarily in a direction parallel to punch travel. Parts produced by impact extrusion are essentially longitudinally oriented, for example, collapsible tubes and cans.

Originally used only on soft materials (lead, tin, etc.) to make collapsible tubes, the process has, in recent years, found rapidly increasing applications in the field of metallic containers, as well as in the production of a wide range of automotive, electrical, and hardware components. Aluminum and its alloys, copper, high brasses, and mild steel are impact-extruded commercially in large quantities.

Since it is a “chipless” metalworking process, impact extrusion competes in many applications with the automatic screw machine, deep drawing, die casting, hot forging, cold upsetting, and other operations. To achieve optimum results, it is important that likely parts be designed with an understanding of characteristics of metal flow, die design, and proper distribution of pressures in impact extrusion.

The impact extrusion of unheated slugs is often called *cold extrusion*.

Impact (er) Forging

A forging process in which the component is forged between a pair of moving die faces so both sides of the component are worked.

Impact Line

A blemish on a drawn sheet-metal part caused by a slight change in metal thickness. The mark is called an impact line when it results from the impact of the punch on the blank; it is called a recoil line when it results from transfer of the blank from the die to the punch during forming or from a reaction to the blank being pulled sharply through the *draw ring*.

Impact Load

An especially severe shock load such as that caused by instantaneous arrest of a falling mass, by shock meeting of two parts (e.g., in a mechanical hammer), or by explosive impact, in which there can be an exceptionally rapid buildup of stress.

Impact Sintering

An instantaneous sintering process during *high-energy rate compacting* that causes localized heating, welding, or fusion at the particle contacts.

Impact Strength

A measure of the resiliency or toughness of a solid. The maximum force or energy of a blow (given by a fixed procedure) that can be withstood without fracture, as opposed to fracture strength under a steady applied force.

Impact Test

A test for determining the energy absorbed in fracturing a test piece at high velocity, as distinct from static test. The test may be carried

out in tension, bending, or torsion, and the test bar may be notched or unnotched. See also *Charpy test*, *impact energy*, and *Izod test*.

Generally, any test in which the load is dynamic rather than static. More specifically, a test in which a specially machined test piece is dynamically loaded in a purpose-made machine that registers the energy absorbed in causing failure as a measure of the material toughness. The test pieces usually have a single V notch to initiate the fracture, hence the term V notch test, but less common variations include plain bar tests and keyhole-shaped notch tests. The two most popular testing machines are the Charpy and the Izod. Both of these utilize a weighted pendulum carrying a striker that impacts the test piece located at the low point of the swing. The Izod striking energy is 167 J (120 ft lb) and that of the Charpy 300 J (220 ft lb). The test is commonly used for steels as many exhibit a dramatic reduction in toughness as the temperature falls. This reduction, reflecting a change in fracture mode from ductile to brittle, is measured by recording the energy absorbed by a series of test pieces broken over a range of temperature. In addition, the characteristics of the fracture faces may be examined to determine the relative proportions of the ductile and brittle (or crystalline) zones. The observations provide another measure of the change from brittle to ductile behavior by identifying the temperature at which a fracture is 50% ductile and 50% brittle. This temperature is termed either the fracture appearance transition temperature or the ductile/brittle transition temperature. Reference may also be made to the nil ductility transition temperature, which is the highest temperature at which no ductile fracture is observed. This latter term is sometimes also applied to the temperature at which some specified low level of impact strength is recorded, for example, 10 ft lb in the Charpy test. See *brittle fracture*.

Impact Tube

Same as *Pitot tube*.

Impact Value

The energy absorbed by a specimen of standard design when sheared by a single blow from a testing machine hammer. Expressed in J/m² or ft·lb in.²

Impact Velocity

The relative velocity between the surface of a solid body and an impacting liquid or solid particle. To describe this velocity completely, it is necessary to specify the direction of motion of a particle relative to the solid surface in addition to the magnitude of the velocity. The following related terms are also in use: (1) absolute impact velocity, the magnitude of the impact velocity, and (2) normal impact velocity, the component of the impact velocity that is perpendicular to the surface of the test solid at the point of impact.

Impact Wear

Wear of a solid surface resulting from repeated collisions between that surface and another solid body. The term *erosion (erosive) wear* is preferred in the case of multiple impacts and when the impacting body or bodies are very small relative to the surface being impacted.

Impactation Ratio

See *collection efficiency*.

Imperfection

(1) When referring to the physical condition of a part or metal product, any departure of a quality characteristic from its intended level or state. The existence of an imperfection does not imply nonconformance (see *nonconforming*) nor does it have any implication as to the usability of a product or service. An imperfection must be rated on a scale of severity, in accordance with applicable specifications, to establish whether or not the part or metal product is of acceptable quality. (2) Generally, any departure from an ideal design, state, or condition. (3) (In crystal lattice) Any deviation from perfection in lattice alignment such as a dislocation or any atomic imperfection such as a substitutional or interstitial atom in a solid solution or a vacancy.

Impingement

A process resulting in a continuing succession of impacts between liquid or solid particles in a solid surface. In preferred usage, impingement also connotes that the impacting particles are smaller than the solid surface and that the impacts are distributed over the surface or a portion of the surface. If all impacts are superimposed on the same point or zone, then the term repeated impact is preferred.

Impingement Corrosion Attack

A form of surface damage occurring in flowing liquids resulting from entrained particles or turbulent flow and associated bubbles abrading or disrupting the normally protective surface oxide film. The exposed metal is anodic to the neighboring oxide and hence is preferentially corroded; see *electrochemistry*. Generalizing the likelihood and severity of attack is increased by increases in fluid velocity, fluid contamination, (suspended, dissolved, or deposited), and surface roughness and irregularities in the system such as bends and inlets to tubes. See also *corrosion-erosion* and *cavitation*.

Impingement Erosion

Loss of material from a solid surface due to *liquid impingement*. See also *erosion*.

Impingement Umbrella

The partial screening of the surface of a solid specimen subjected to solid impingement that sometimes occurs when some of the solid particles rebound from the surface and impede the motion of other impinging particles.

Implant

A manufactured device inserted into the human body to replace or reinforce some structure or undertake some function.

Impregnate

In reinforcing plastics, to saturate the reinforcement with a resin.

Impregnated Fabric

A fabric impregnated with a synthetic resin. See also *pregreg*.

Impregnated Wood

Also called *compressed wood* or *densified wood*. Many types are forms of laminated wood. *Compreg*, developed by U.S. Forest Products Laboratory, consists of many layers of 0.0625 in. (0.16 cm), rotary cut, yellow-birch plies bonded with about 30% resin under a pressure of 600–1500 lb/in.² (4–10 MPa).

Wood impregnated with *polyethylene glycol* is known as “Peg.” This treatment is used for walnut gunstocks for high-quality rifles and for tabletops. This impregnant can be used to reduce checking of green wood during drying. Wood can also be vacuum-impregnated with certain liquid vinyl monomers and then treated by radiation or catalyst heat systems, which transform the vinyl to a plastic. *Methyl methacrylate*, or *acrylic*, is a common resin used to produce this type of product, known as *wood-plastic combinations* (WPCs). A principal commercial use of this modified wood is as parquet flooring and for sporting goods such as archery bows. WPC material resists indentation from rolling, concentrated, and impact loads better than white oak. This is largely due to improved hardness, which is increased 40%. Abrasion resistance is no better than that of white oak.

Impregnating Materials for Castings

Castings are impregnated for several reasons, the most obvious of which is to prevent leakage. Other important reasons for impregnating are to prevent corrosion, improve surface finish, remove sites that may lodge food particles and cause bacterial growth, and prevent back seepage of occluded fluids. Leakage may be avoided by blocking the pores at any point along their length, whereas all of the other aims can be met only when the pores are blocked at the surface as well as in depth.

Impregnating Process

There are four stages in the impregnation process. First, a porous casting may have different types of porosity (continuous, noncontinuous or blind, and isolated). After evacuation and impregnation under pressure, an ideal condition that is rarely attained may be found; however, it is more likely that there is bleeding.

Bleeding will lead to incompletely filled pores near the surface; and contraction in curing will lead to incomplete filling along the length of the pore. The latter condition may arise from loss of solvent from impregnants introduced as a solution, loss of water from vehicles such as sodium silicate, and decomposition of organic impregnants by exposure to excessive temperatures (carbonization). Some compensation for the loss of solvent or water can be obtained if the residue can be made to expand on curing, for example, by oxidation of metallic particles carried in sodium silicate.

It has been demonstrated that the sealing action of an impregnant generally decreases as the amount of volatile in the formulation increases. One exception to this rule has been demonstrated, in which a self-fluxing brazing filler metal powder is fused in the pores after evaporation of the vehicle. The molten braze filler metal runs into the narrowest part of the pore under capillary action and gives optimum sealing in spite of incomplete filling of the pores.

Impregnating Materials

The oldest method of reducing leakage, particularly in cast iron, is to rust or oxidize the pores, sometimes after “impregnation” with mud. Natural drying oils such as tung and linseed were also among the first impregnant materials to be used. Another early type of impregnant was based on the readily available water glass (sodium silicate).

The contraction of sodium silicate impregnants during drying was reduced by the addition of inert particles such as asbestos, chalk, or oxides. Further development has led to the so-called metallic impregnants in which a large proportion of the solids are metal powders (e.g., copper or iron). Special agents are added to the sodium silicate to reduce sedimentation. During the curing of these “metallic” impregnants, the metal particles oxidize so that a certain amount of expansion occurs to offset the considerable contraction. However, these impregnants have several disadvantages; their resistance to high temperatures is poor (e.g., 149°C max); the impregnants are attacked by steam; and the abrasive oxides make them unsuitable for bearings or machining.

There are several differences between the sodium silicate and plastic impregnants. In general, because plastics or oils do not wet castings readily, a vapor degreasing is usually necessary, followed by pumping under a vacuum of at least 712 mmHg for periods of 30 min (one impregnator has achieved success in difficult cases by holding under a vacuum of 10 μ m for 2 h). A second difference results from the higher viscosity of plastics. During the pressure stage of impregnation, a minimum of 30 min under pressure may be necessary to force the plastics to flow deeply into the pores. One solution to the problem of high viscosity is to thin the plastic by solvents, but this leads to bleeding and contraction.

The cost of impregnating with sodium silicate is usually less (about one quarter less) than with plastics because prior cleaning of castings needs to be less thorough and excess impregnant is washed away with water.

The most important types of plastic impregnants are based on the styrene monomer. A typical composition of this substitute is 80% styrene monomer with 20% linseed oil and a small quantity of organic oxidizer as a catalyst. The instability of the catalyst in the presence of lead, zinc, and copper restricts the use of this type of impregnant primarily to the light metals. The castings are heated for 2 h at 135°C to polymerize the impregnant.

The thermosetting of plastics formed by copolymerization of the styrene monomer with polyesters represents an advance on the styrene–linseed oil polymers because it is possible to introduce liquid bath curing. The surfaces are cured rapidly when they make contact with the liquid curing agent, so that subsequent bleeding (which occurs on curing in ovens) is prevented. Other improvements that have been introduced with the styrene–polyester plastics include detergent washing (does not wash the impregnant from pores), freedom from inhibition by copper, and low contraction on curing (e.g., 6%–7%). A typical curing cycle is 1 h at 135°C. These impregnants will withstand 260°C for short periods and 204°C in continuous service.

Phenolics, epoxy, and furfural plastics can also be used for impregnation. The phenolics are dissolved in a solvent such as alcohol and require curing into stages, first to remove the alcohol (e.g., 1 h at 80°C) and second to cure the plastic (e.g., 3 h at 190°C). Phenolic resins do not have good adherence to metal, and they seal according to bleeding and contraction. Therefore, they do not provide the highest quality seals, although they may be suitable for many types of work. Epoxy resins have good adhesion to metals and resistance to chemicals, but many have to be thinned with solvents to achieve low viscosity so that the impregnation occurs readily. Furfural-type plastics have been developed for resistance to alkalis.

Polyester–styrene and sodium silicate are the most widely used impregnants. The plastics give the higher-quality seal, but sodium silicate continues to be used because of its low cost.

Impregnation

(1) Treatment of porous castings with a sealing medium to stop pressure leaks. (2) The process of filling the pores of a sintered compact,

usually with a liquid such as a lubricant. (3) The process of mixing particles of a nonmetallic substance in a cemented carbide matrix, as in diamond-impregnated tools.

Impressed Current

Direct current supplied by a device employing a power source external to the electrode system of a *cathodic protection* insulation.

Impression

(1) In electron microscopy, the reproduction of the surface contours of a specimen formed in a plastic material after the application of pressure, heat, or both. (2) In hardness testing, the imprint or dent made in the specimen by the indenter of a hardness-measuring device. See also *indentation hardness* and *indenter*. (3) A cavity machined into a forging die to produce a desired configuration in the workpiece during forging.

Impression-Die Forging

A forging that is formed to the required shape and size by machined impressions in specially prepared dies that exert 3D control on the workpiece.

Impression Replica

A surface replica made by impression. See also *impression* and *replica*.

Impulse (Resistance Welding)

An impulse of welding current consisting of a single pulse or a series of pulses, separated only by an interpulse time.

Impurities

(1) Elements or compounds with presence in a material that is undesirable. (2) In a chemical war material, minor constituent (s) or component (s) not included deliberately; usually, to some degree or above some level, undesirable.

Inadequate Joint Penetration

Weld joint penetration that is less than that specified.

Incandescence

The omission of light radiation by a substance at elevated temperature, above 540°C in dim background light.

Inclinable Press

A press that can be inclined to facilitate handling of the formed parts. See also *open-back inclinable press*.

Inclined Position

The position of a pipe joint in which the axis of the pipe is at an angle that is approximately 45° to the horizontal and the pipe is not rotated during welding. A loose term for welding positions

not lying within the limits of the four basic positions: flat, vertical, horizontal, and overhead.

Included Angle

See preferred term *groove angle*.

Inclusion

(1) A physical and mechanical discontinuity occurring within a material or part, usually consisting of solid, encapsulated foreign material. Inclusions are often capable of transmitting some structural stresses and energy fields, but to a noticeably different degree than from the parent metal. (2) Particles of foreign material in a metallic matrix. The particles are usually compounds, such as oxides, sulfides, or silicates, but may be of any substance that is foreign to (and essentially insoluble in) the matrix. See also *exogenous inclusion*, *indigenous inclusion*, and *stringer*.

Inclusion Count

Determination of the number, kind, size, and distribution of nonmetallic inclusions in metals.

Incoherent Scattering

In materials characterization, the deflection of electrons by electrons or atoms that results in a loss of kinetic energy by the incident electrons. See also *coherent scattering*.

Incoloy and Inconel

Ranges of proprietary alloys based on nickel with major additions of other elements. In particular, chromium and iron but also molybdenum, cobalt, titanium, aluminum, etc. Generalizing, they have good corrosion resistance including resistance to oxidation at high temperatures.

Incomplete Fill (of Weld)

An insufficient quantity of filler material in a welded joint, particularly a butt joint. Same as *underfill*.

Incomplete Fusion (of Weld)

Same as *lack of fusion*.

Increment

An individual portion of a material collected by a single operation of a sampling device from parts of a lot separated in time or space. Increments may be tested individually or combined (composited) and tested as a unit.

Incubation Period

(1) A period prior to the detection of corrosion while the metal is in contact with a corrodent. (2) In cavitation and impingement erosion, the initial stage of the erosion rate-time pattern during which the erosion rate is zero or negligible compared to later stages. (3) In cavitation and impingement erosion, the exposure duration associated with the initial stage of the erosion rate-time pattern during

which the erosion rate is zero or negligible compared to later stages. See also *cavitation erosion* and *impingement erosion*.

Indentation

In a spot, seam, or projection welding, the depression on the exterior surface of the base metal.

Indentation Hardness

(1) The resistance of a material to indentation. This is the usual type of hardness test, in which a pointed or rounded indenter is pressed into a surface under a substantially static load. (2) Resistance of a solid surface to the penetration of a second, usually harder, body under prescribed conditions. Numerical values used to express indentation hardness are not absolute physical quantities, but depend on the hardness scale used to express hardness. See also *Brinell hardness test*, *Knoop hardness test*, *nanohardness test*, *Rockwell hardness test*, and *Vickers hardness test*.

Indenter

In hardness testing, a solid body of prescribed geometry, usually chosen for its high hardness, that is used to determine the resistance of a solid surface to penetration.

Index of Refraction

See *refractive index*.

Indication

In inspection, a response to a nondestructive stimulus that implies the presence of an *imperfection*. The indication must be interpreted to determine if (a) it is a true indication or a *false indication* and (b) whether or not a true indication represents an unacceptable deviation.

Indicator

A substance that, through some visible change such as color, indicates the condition of a solution or other material as to the presence of free acid, alkali, or other substance.

Indices

See *Miller indices*.

Indigenous Inclusion

An *inclusion* that is native, innate, or inherent in the molten metal treatment. Indigenous inclusions include sulfides, nitrides, and oxides derived from the chemical reaction of the molten metal with the local environment. Such inclusions are small and require microscopic magnification for identification. Compare with *exogenous inclusion*.

Indigo

One of the most important of all vegetable dyestuffs and valued for the beauty and permanence of its color. It is widely used to color *denim* for clothing. Commercial blue indigo is obtained from plants

I and several other species, of India and Java, and the plants of Europe, by steeping the freshly cut plants in water, and after decomposition of the glucoside *indican*, the liquid is run into beating vats where the indigo separates out in flakes that are pressed into cakes. *Indigo red* is a crimson dyestuff obtained in the proportion of 1%–5% in the manufacture of indigo by extraction in inorganic solvents. *Indigo brown* is an impurity that occurs during the manufacture of indigo, but has little influence in the dyeing process. Other constituents are *indigo yellow* and *indigo gluten*. *Indigo white* is obtained by reducing agents and an alkali.

Indirect-Arc Furnace

An electric-arc furnace in which the metallic charge is not one of the poles of the arc.

Indirect (Backward) Extrusion

See *extrusion*.

Indirect Sintering

A process whereby the heat needed for sintering is generated outside the body and transferred to the powder compact by conduction, convection, radiation, etc. Contrast with *direct sintering*.

Indium

Indium (symbol In) is a silvery white metal with a bluish hue, whiter than tin. It has a specific gravity of 7.31, tensile strength of 103 MPa, and elongation 22%. It is very ductile and does not work-harden, because its recrystallization point is below normal room temperature, and it softens during rolling. The metal is not easily oxidized, but above its melting point, 157°C, it oxidizes and burns with a violet flame.

Indium is now obtained as a by-product from a variety of ores. Because of its bright color, light reflectance, and corrosion resistance, it is valued as a plating metal, especially for reflectors. It is softer than lead, but a hard surface is obtained by heating the plated part to diffuse the indium into the base metal. It has high adhesion to other metals. When added to chromium plating baths, it reduces brittleness of the chromium.

In spite of its softness, small amounts of indium will harden copper, tin, or lead alloys and increase the strength. About 1% in lead will double the hardness of the lead. In solders and fusible alloys, it improves wetting and lowers the melting point. In lead-base alloys, a small amount of indium helps to retain oil film and increases the resistance to corrosion from the oil acids. Small amounts may be used in gold and silver dental alloys to increase the hardness, strength, and smoothness. Small amounts are also used in silver-lead and silver-copper aircraft-engine bearing alloys. Lead-indium alloys are highly resistant to corrosion and are used for chemical-processing equipment parts. Gold-indium alloys have a high fluidity, a smooth lustrous color, and good bonding strength. An alloy of 77.5% gold and 22.5 indium, with the working temperature of about 500°C, is used for brazing metal objects with glass inserts. Silver-indium alloys have a high hardness and a fine silvery color. A silver-indium alloy used for nuclear control rods contains 80% silver, 15% indium, and 5% cadmium. The melting point is 746°C, tensile strength 289 MPa, and elongation 67%, and it retains a strength of 120 MPa at 316°C. It is stable to irradiation and is corrosion resistant

to high-pressure water up to 360°C. The thermal expansion is about six times that of steel.

Mechanical Properties

Typical properties of annealed indium are as follows: tensile strength, 262 MPa; hardness, 0.9 Bhn; and compressive strength, 215 MPa.

Because indium does not work-harden and almost all of the deformation occurring in the tensile test is localized, deformation is very low for such a low-strength material.

Reactivity

Indium is stable in dry air at room temperature. The metal boils at 2000°C but sublimates when heated in hydrogen or in vacuum. Because a thin, tenacious oxide film forms on its surface, indium resists oxidation up to, and a little beyond, its melting point. The film, however, dissolves in dilute hydrochloric acid.

Indium can be slowly dissolved in dilute mineral acids and more readily in hot dilute acids. It unites with the halogens directly when warm. Concentrated mineral acids react vigorously with indium, but there is no attack by solutions of strong alkalies. The metal dissolves in oxalic acid, but not in acetic acid.

There is no evidence that the metal is toxic and it has no action as a skin irritant.

Applications

The three largest uses of indium are in semiconductor devices, bearings, and low-melting-point alloys.

Semiconductors

Indium is used to form p–n junctions in germanium. Two characteristics—the fact that indium readily wets the germanium and dissolves it at 500°C–550°C, as well as the fact that after alloying, the indium does not set up contraction stresses in the germanium—make it suitable for this application.

If a piece of n-type germanium is dissolved in indium, germanium containing excess indium recrystallizes after subsequent cooling. The excess indium changes the germanium from n-type to p-type.

Other compounds include InSb where interest is twofold. Its small energy gap (0.18 eV) makes it valuable as a photodetector in wavelengths from the infrared up to ~8 mm. InSb also has a very high electron mobility—up to 80,000 cm²/Vs at room temperature and up to 800,000 cm²/Vs at liquid nitrogen temperature. Consequently, the material can be used in devices based on magnetoresistance or the Hall effect (gyrators, switching elements, magnetometers, analog computers, etc.).

InAs is of interest as a semiconductor: energy gap ~0.47 eV and electron mobility ~50,000 cm²/Vs (room temperature). The energy gap is too small to make InAs practical as a transistor material. It is, however, a candidate for infrared photoconductor applications. The relatively high mobility and small dependence of electrical properties on temperature make InAs a particular interest for Hall effect and magnetoresistance devices.

InO₃ is an n-type semiconductor finding use as a resistive element in integrated circuits, and InP is a semiconductor that is useful for rectifiers and transistors and is a promising material for electronic devices that operate at intermediate temperatures.

Bearings

Impregnating the surface of steel-backed lead–silver bearings increases the strength and hardness, improves resistance to corrosion by acids in the lubricants, and permits better retention of the bearing oil film. Indium-coated bearings can be used for high-duty service such as found in aircraft engines and diesel engines.

Alloying

A common glass sealing alloy contains approximately 50% tin–50% indium. A solder alloy containing 37.5% lead, 37.5% tin, and 25% indium has greater resistance to alkalis than the 50% lead–50% tin solder.

Adding indium to gold for use in dental alloys increases the tensile strength and ductility of gold, improves resistance to discoloration, and improves bonding characteristics.

Individuals

Conceivable constituent parts of a population. See also *population*.

Induction Bonding

The use of high-frequency (5–7 MHz) electromagnetic fields to heat a bonding agent placed between the plastic parts to be joined. The bonding agent consists of micro-sized ferromagnetic particles dispersed in a thermoplastic matrix, preferably the parent material of the parts to be bonded. When this binder is exposed to the high-frequency source, the ferromagnetic particles respond and melt the surrounding plastic matrix, which in turn melts the interface surfaces of the parts to be joined.

Induction Brazing

A brazing process in which the surfaces of components to be joined are selectively heated to brazing temperature by electrical energy transmitted to the workpiece by induction, rather than by a direct electrical connection, using an inductor or work coil.

Induction Furnace

An alternating current electric furnace in which the primary conductor is coiled and generates, by electromagnetic induction, a secondary current that develops heat within the metal charge. There are two classifications of induction furnaces: coreless and channel. In a coreless furnace, the refractory-lined crucible is completely surrounded by a water-cooled copper coil, while in the channel furnace, the coil surrounds only a small appendage of the unit, called an inductor. The term “channel” refers to the channel that the molten metal forms as a loop within the inductor. It is this metal loop that forms the secondary of the electrical circuit, with the surrounding copper coil being the primary. In a coreless furnace, the entire metal content of the crucible is the secondary. See also *coreless induction furnace*.

Induction Hardening/Heating/Melting

Processes in which heating is by the electrical induction of eddy currents in the material being treated. The general principle is that the material is surrounded by a water-cooled conducting coil carrying ac current. Eddy currents are induced in the material causing

heating. Low- and medium-frequency currents up to about 100 kHz cause general heating through the thickness or volume of material and hence are used for melting and billet heating applications. Higher frequencies induce current at the surface, the so-called skin effect, and hence are useful for case hardening.

Induction Heating

Heating by combined electrical resistance and hysteresis losses induced by subjecting a metal to the varying magnetic field surrounding a coil carrying alternating current. See Table I.1.

Induction Melting

Melting in an *induction furnace*.

Induction Sintering

Sintering in which the required heat is generated by subjecting the compact to electromagnetic induction. See also *direct sintering*.

Induction Soldering

A soldering process in which the heat required is obtained from the resistance of the work to induce electric current.

Induction Tempering

Tempering of steel using low-frequency electrical *induction heating*.

Induction Welding

Processes in which the heat for welding is induced by an alternating electric current. A forging action is also normally applied to effect the joint. If the ac frequency is 10 Hz or higher, the process can be termed inelasticity. See *anelasticity*.

Induction Work Coil

The *inductor* used when induction heating and melting as well as induction welding, brazing, and soldering.

Inductively Coupled Plasma

An argon plasma excitation source for atomic emission spectroscopy or mass spectroscopy. It is operated at atmospheric pressure and sustained by inductive coupling to a radio-frequency electromagnetic field. See also *radiofrequency*.

Inductor

A device consisting of one or more associated windings, with or without a magnetic core, for introducing inductance into an electric circuit.

Industrial Atmosphere

An atmosphere in an area of heavy industry with soot, fly ash, and sulfur compounds as the principal constituents.

Industrial Jewels

Hard stones, usually *ruby* and *sapphire*, used for bearings and impulse pins in instruments and for recording needles. *Ring jewels* are divided into large and small. The large rings are about 0.050 in. (0.127 cm) in diameter and 0.012 in. (0.030 cm) thick with holes above 0.006 in. (0.015 cm) in diameter. Ring jewels are used as pivot bearings in instruments, timepieces, and dial indicators. From 2 to 14 are used in a watch. *Vee jewels* are used in compasses and electrical instruments. *Cup jewels* are used for electric meters and compasses. *End stones* are flat, undrilled stones with polish faces to serve as end bearings. *Pallet stones* are rectangular impulse stones for watch escapements. *Jewel pins* are cylindrical impulse stones for timepiece escapements. In making *bearing jewels*, the synthetic sapphire boules are split in half, secured to wooden blocks, and then sawed to square blanks. These are then rounded on centerless grinding machines and flat-ground to thickness by means of copper wheels and diamond powder. *Quartz bearings* are made from fused quartz rods. A notch is ground in the end of the rod and then polished and cut off, repeating the process for each bearing. Quartz has a Mohs hardness of only 7, while the synthetic ruby and sapphire have a Mohs hardness of 8.8, but Quartz has the advantage of low thermal expansion.

The making of industrial jewels was formally a relatively small, specialized industry, and a national stockpile of cut jewels was maintained for wartime emergencies. But the process of slicing and shaping hard crystals for semiconductors and other electronic uses is essentially the same, and stones of any required composition and cut to any desired shape are now regularly manufactured.

Industrial Thermosetting Laminates

So-called industrial thermosetting laminates are those in which a reinforcing material has been impregnated with thermosetting resins, and the laminates have usually been formed at relatively high pressures.

Resins most commonly used are phenolic, polyester, melamine, epoxy, and silicone; reinforcements are usually paper, woven cotton, asbestos, glass cloth, or glass mat.

The National Electrical Manufacturers' Association has published standards covering many standard grades of laminates. Each manufacturer, in addition to these, normally provides a range of special grades with altered or modified properties or fabricating characteristics. Emphasis here is on the standard grades available.

Laminates are available in the form of sheet, rod, and rolled or molded tubing. Laminated shapes can also be specified; these are generally custom-molded by the laminate producer.

General Properties

Resin binders generally provide the following characteristics: (1) phenolics are low in cost, have good mechanical and electrical properties, and are somewhat resistant to flame; (2) polyesters used with glass mat provide a low-cost laminate for general-purpose uses; (3) epoxy resins are more expensive, but provide a high degree of resistance to acids, alkalies, and solvents, as well as extremely low moisture absorption, resulting in excellent mechanical and electrical property retention under humid conditions; (4) silicones, high in cost, provide optimum heat resistance; and (5) melamines provide resistance to flame, alkalies, arcing, and tracking, as well as good colorability.

Mechanical Properties

Tensile strengths of paper, asbestos, and cotton fabric-base laminates vary from about 136 to over 552 MPa; flexural strengths are somewhat higher and the moduli of elasticity are about 7,000–14,000 MPa.

Other Properties

In general, moisture absorption is about 0.3%–1.3% (24 h, 1.5 mm thickness), depending on resin and reinforcement.

Heat resistance depends on both resin and reinforcements. Most standard laminates are designed for a variety of insulation requirements. Generally, maximum continuous service temperatures are about 121°C for phenolics reinforced with organic reinforcements; 149°C for phenolics, melamines, and epoxies reinforced with inorganic materials; and 260°C for silicones reinforced with inorganic materials.

Flame retardance of most standard grades other than melamines is relatively poor; but special flame-resistant or self-extinguishing grades are available.

Glass cloth reinforcements provide tensile strength values in the 92–255 MPa range; modulus of elasticity can approach 20,600 MPa. Typical flatwise compression strength values fall in the 160–340 MPa range.

Electrical Properties

Dielectric strengths (perpendicular to laminates) generally range between 400 and 700 V/mil and up to 1000 V/mil for paper-based phenolics. Dissipation factor, as-received and at 10⁶ cps, ranges from as high as 0.055 for cotton-based phenolics to as low as 0.0015 for a glass-reinforced silicone laminate.

Inelastic Electron Scatter

See *incoherent scattering*.

Inelastic Scattering

Any collision or interaction that changes the energy of an incident particle. Contrast with *elastic scattering*.

Inert

Unreactive, stable, or indifferent to the presence of other materials. A relative term, usually applying under some limited set of circumstances or application.

Inert Anode

An *anode* that is insoluble in the *electrolyte* under the conditions prevailing in the *electrolysis*.

Inert Filler

A Filler material added to a plastic to alter the end-item properties through physical rather than chemical means.

Inert Gas

(1) A gas, such as helium, argon, or nitrogen, that is stable, does not support combustion, and does not form reaction products with other materials. (2) In welding, a gas that does not normally combine chemically with the base metal or filler metal. (3) In processing of

plastics, a gas (usually nitrogen) that does not absorb or react with ultraviolet light in a curing chamber.

Inert Gas Fusion

An analytical technique for determining the concentrations of oxygen, hydrogen, and nitrogen in a sample. The sample is melted in a graphite crucible in an inert gas atmosphere; individual component concentrations are detected by infrared or thermal conductive methods.

Inert Gas Metal Arc Welding

See preferred term *gas metal arc welding*.

Inert Gas Shielded Cutting/Welding

Processes in which the heat source is an electric arc and the cutting/welding zone is protected from the environment by an inert gas such as argon.

Inert Gas Tungsten Arc Welding

See preferred term *gas tungsten arc welding*.

Infiltrant

Material used to infiltrate a porous powder compact. The infiltrant as positioned on the compact is called a slug. See also *contact infiltration*.

Infiltration

(1) The process of filling the pores of a sintered or unsintered compact with a metal or alloy of lower melting temperature. See also *contact infiltration*. (2) In particular, a metal introduced in the molten state and entering by capillary action.

Inflection Point

Position on a curved line, such as a phase boundary on a *phase diagram*, at which the direction of curvature is reversed.

Infrared

Pertaining to that part of the electromagnetic spectrum between the visible light range and the radar range. Radiant heat is in this range, and infrared heaters are frequently used in the thermoforming and curing of plastics and composites. Infrared analysis is used for identification of polymer constituents.

Infrared Analyzer

An atmosphere-monitoring device that measures a gas (usually carbon monoxide, carbon dioxide, and methane) presence based on specific wavelength absorption of infrared energy.

Infrared Brazing

A brazing process in which the heat required is furnished by infrared radiation.

Infrared Radiation

Electromagnetic radiation in the wavelength range of 0.78–300 μm (7800 to 3×10^6 Å). See also *electromagnetic radiation*, *far-infrared radiation*, *middle-infrared radiation*, and *near-infrared radiation*.

Infrared Soldering

A soldering process in which the heat required is furnished by infrared radiation.

Infrared Spectrometer

A device used to measure the amplitude of electromagnetic radiation of wavelengths between visible light and microwaves.

Infrared Spectroscopy

The study of the interaction of material systems with electromagnetic radiation in the infrared region of the spectrum. The technique is useful for determining the molecular structure of organic and inorganic compounds by identifying the rotational and vibrational energy levels associated with the various molecules.

Infrared Spectrum

(1) The range of wavelengths of infrared radiation. (2) A display or graph of the intensity of infrared radiation emitted or absorbed by a material as a function of wavelength or some related parameter.

Ingate

Same as *gate*.

Ingot

A casting of simple shape that will be subjected to further working operations like hot working or remelting. The as-cast ingot is normally cropped to remove the top section containing impurities and other defects.

Ingot Iron

Nearly chemically pure *iron* made by the basic open-hearth process and highly refined, remaining in the furnace 1–4 h longer than the ordinary time and maintained at a temperature of 2900°F–3100°F (1593°C–1704°C). In England, it is referred to as *mild steel*, but in the United States, the line between iron and steel is placed arbitrarily at about 0.15% carbon content. Ingot iron has as low as 0.02% carbon. It is obtainable regularly in grades 99.8%–99.9% pure iron. Ingot iron is cast into ingots and then rolled into plates or shapes and bars. It is used for construction work where a ductile, rust-resistant metal is required, especially for tanks, boilers, enameled ware, and galvanized culvert sheets. The tensile strength, hot rolled, is 48,000 lb/in.² (331 MPa), elongation 30%, and Brinell hardness 82–100. Dead soft, the tensile strength is 38,500 lb/in.² (265 MPa), elongation 45%, and Brinell hardness 67. *Armco ingot iron*, of Armco Steel Corp., is 99.94% pure, with 0.013% carbon and 0.017% manganese. It is used as a rust-resistant construction material, for electromagnetic cores, and as a raw material for making special steels. The specific

gravity is 7.858 and melting 2768°F (1530°C). *Enamelite* is a sheet iron especially suited for vitreous enameling. Ingot iron may also be obtained in grades containing 0.25%–0.30% copper, which increases the corrosion resistance. Iron of very low carbon content may also be used for molds and dies that are to be hobbled. The iron is quite plastic under the hob and is then hardened by carburizing. *Plastiron* is such an iron.

Ingot Mold

The substantial vessel into which molten metal is poured to solidify as an ingot.

Ingotism

Excessively large grain size in castings, usually the result of casting at too high a temperature.

Inherent (Austenitic) Grain Size

The austenitic grain size developed in steel when cast.

Inhibitor

A substance that retards some specific chemical reaction. Picking inhibitors retard the dissolution of metal without hindering the removal of scale from steel. Inhibitors are also used in certain types of monomers and resins to prolong storage life.

Initial Current

The current after starting, but before establishment of welding current.

Initial Modulus

The slope of the initial straight portion of a stress–strain or load–elongation curve. See also *Young's modulus*.

Initial Pitting

Surface fatigue occurring during the early stages of gear operation, associated with the removal of highly stressed local areas and *running-in*.

Initial Recovery

The decrease in strain in a solid during the removal of force before any creep recovery takes place, usually determined at constant temperature. Sometimes referred to as instantaneous recovery.

Initial Strain

The strain produced in a specimen by given loading conditions before creep occurs.

Initial Stress

The stress produced by strain in a specimen before stress relaxation occurs. Also called instantaneous stress.

Initial Tangent Modulus

The slope of the stress–strain curve at the beginning of loading. See also *modulus of elasticity*.

Initiation of Stable Crack Growth

The initiation of slow stable crack advance from the blunted crack tip.

Initiator

Sources of free radicals, often peroxides or azo compounds. They are used in free-radical polymerizations, for curing thermosetting resins, and as cross-linking agents for elastomers and cross-linked polyethylene.

Injection Blow Molding

A *blow molding* process in which an injection-molded preform is used instead of an extruded parison.

Injection Molding (Ceramics)

A process for forming ceramic articles in which a granular ceramic-binder mix is heated until softened and then forced into a mold cavity, where it cools and resolidifies to produce a part of the desired shape.

Injection Molding (Metals)

A process similar to plastic injection molding using a plastic-coated metal powder of fine particle size (~10 μm).

Injection Molding (Plastics)

Method of forming a plastic to the desired shape by forcing the heat-softened plastic into a relatively cool cavity under pressure. See also *thermoplastic injection molding* and *thermoset injection molding*.

Injection Molding

Injection molding of plastics is analogous to die casting of metals. The plastic is heated to a fluid state in one chamber and then forced at high speed into a relatively cold, closed mold where it cools and solidifies to the desired shape. This method of processing plastics became a commercial reality in the early 1930s. It is the fastest and most economical of all commercial processes for the molding of thermoplastic materials and is applicable to the production of articles of intricate as well as simple design.

A slightly modified version of injection molding known as “jet molding” is applicable to the molding of thermosetting materials. The principal difference between the two processes is the function of the temperature of the nozzle and mold on the material. Injection molding employs a relatively cold mold to solidify thermoplastics by chilling the mass below the melting point. Jet molding employs a relatively hot nozzle and mold to harden the thermosetting material by completing the cure.

Process

The sequence of operation known as the molding cycle is as follows:

1. Two mold halves that, when closed together, combine to form one or more negative forms of the article to be molded are tightly clamped between the platens of an injection-molding machine.
2. The closed mold is brought into contact with the nozzle orifice of a heating chamber. The heating chamber, known as the plastifying cylinder, is of sufficient size to carry an inventory of material equal to several volumes required to fill the mold. This permits gradual heating of the plastic to fluidity.
3. An automatically weighed or measured quantity of granulated thermoplastic, sufficient to fill the mold cavity, is fed into the rear of the plastifying cylinder.
4. A reciprocating plunger actuated by a hydraulically operated piston forces the material into the plastifying cylinder. An equal quantity of fluid plastic is thus forced out of the front of the cylinder through the nozzle orifice and into the mold.
5. A pressure of several thousand megapascals is maintained on the material within the mold until the plastic cools and solidifies.
6. After the molded item has hardened sufficiently to permit removal from the mold without distortion, the mold is opened and the part ejected.

Injection molding offers several advantages over other methods of molding. Some of the more important of these are as follows:

1. The process lends itself to complete automation for the molding of a great number of parts.
2. Mold parts require little if any postmolding operations.
3. High rates of production are made possible by the high thermal efficiency of the operation and by the short molding cycles possible.
4. There is a low ratio of mold-to-part cost in large volume production.
5. Long tool and machine life requires a minimum of maintenance and relatively low amortization costs.
6. Reuse of material is possible in most applications.

Molding machines vary considerably in design as well as capacity. For example, the clamp mechanism may be hydraulically operated, hydraulic-mechanically operated, or entirely mechanical. The injection of the material into the mold may be accomplished by a rotating screw as well as a plunger.

Machines are rated according to the weight of plastic that can be injected into the mold (the shot) with one stroke of the injection plunger. The capacity of commercially available machines covers a range from a fraction of a gram to 12.5 kg.

Limitations

The injection-molding process is subject to the following limitations:

Material: Any thermoplastic material may be a candidate for injection molding. Upon heating, it can be rendered sufficiently fluid to permit injection into a mold, and the resulting molded article retains all the desired properties.

Geometry of part: Any part, regardless of geometry, can be removed from a mold without damage to the mold or part is moldable.

Weight of part: The weight of the part must be within the "shot" rating of the particular machine being used.

Projected area and wall thickness of part: The limitation on these dimensions will be governed by several factors including the relative fluidity of the plastic being molded, the pressure necessary to fill the mold, the rigidity of the part to permit ejection from the mold without deformation, and sufficient clamp force available to hold the mold in a closed position when the necessary injection pressure is developed within the cavity.

Production economy: Economy can be realized only when relatively large quantities are produced. In addition to the material consumed and the cost of the molding operation, the number of pieces produced must also bear the cost of the mold in which they are cast. Depending on the size and complexity of the geometry of the part to be molded, mold costs will vary from a few hundred to many thousands of dollars. Again depending on size and complexity of the part, the rate of production will vary from a few minutes for a single part to several hundreds per minute.

In addition to the high production rates made possible by injection molding, articles of high quality and relatively precise dimensions can be produced. The production of industrial parts held 2D tolerances of ± 0.002 in./in. is quite common.

The injection-molding process has made possible the development of an extremely large family of plastics. The basic types of thermoplastics and the human-modified compositions available are analogous to metals and alloys. New compositions as well as process variations are constantly being developed to meet the demands of particular situations.

Molds

The molds used in injection-molding machines for producing such large automotive components as body panels can now be made more compact and lighter than ever before. What makes this possible is nickel vapor deposition.

For car manufacturers, this means the capital invested in production molding machines can be significantly reduced, or, in more practical terms, it means smaller equipment is needed to handle the molds.

In the manufacture of shell molds, nickel carbonyl vapor is fed into a low-pressure chamber where, at a temperature of 180°C , the vapor decomposes and nickel is deposited, atom by atom, onto a heated metallic master, or mandrel. Carbon monoxide and any unused carbonyl gases are recycled.

The process creates a layer of nickel that is 99.9% pure, at a deposition rate of 0.25 mm/h, faithfully reproducing all surface features. Delivery time for the production of large molds is greatly reduced, compared with conventional mold-making techniques. Uniform wall thicknesses of 1.5–25 mm have been achieved using the vapor deposition method.

A surface hardness of up to $42 R_c$ to a depth of 0.25 mm gives the shell molds excellent wear resistance.

Also, the excellent thermal conductivity of nickel reduces cycle times in the injection-molding process because heat is quickly transferred from the shell to water-cooling channels in the mold assembly.

Nickel has other engineering advantages in shell molds, including its outstanding weldability, the uniform wall thicknesses possible, and the absence of residual stresses.

Recently, a 68,080 kg injection mold was created for the side panels of a prototype composite concept vehicle. Larger components, up to 1.2×2.5 m, can be easily accommodated.

Updated Processes

Injection-compression molding (ICM) has been around for years—in fact, it is how old vinyl records were made. However, with the recent availability of high-speed microprocessors and advanced software to precisely control the molding cycle, the process now works with long-fiber-reinforced thermoplastics. This offers the prospect of stronger and lighter parts, lower costs, and better part-to-part consistency. While standard injection-molding produces reinforced thermoplastic parts with good success, ICM can optimize the performance of long-fiber-reinforced thermoplastic materials.

The difference between ICM and conventional injection molding is that the shot is injected at low pressure into a partially open tool, as opposed to a closed one. The mold closes to compress and distribute the melt into the far reaches of the cavity, thus completing the filling and packing phase. This eliminates molded-in stresses resulting from high injection pressures.

There are two basic types of ICM: sequential and simultaneous. In the latter, compression can begin at any point during injection, and cycle times are similar to those for conventional injection molding. With sequential ICM, the injection stroke ends before compression begins, and cycle times are 1–2 s longer to accommodate secondary clamping motions.

ICM uses significantly lower injection pressures than standard injection molding so longer fibers remain in the finished part. That translates into better mechanical properties. For example, ICM maintains a 12.7 mm fiber length of commercial composites, resulting in finished parts with higher impact strength and more isotropic mechanical properties. In typical applications, impact strength improves 15%–20% in 3.2 mm wall thickness and over 50% and 1.5 mm wall thickness.

Thus, one major benefit of ICM is that it can produce thinner-walled, long-fiber-reinforced parts previously unattainable with injection molding. This is an important consideration in automotive applications where companies want to reduce weight and still maintain high stiffness and impact strength.

However, ICM start-up costs may be higher. The tooling, for example, depending on part and size could cost 10%–15% more. ICM also requires a press with a second-stage compression stroke, as well as precise clamping, accurate shot-size control, and speed control during secondary clamping.

Costs to convert standard injection-molding presses to ICM vary with the type of machine, age, sophistication of the controller, and whether it has precision linear-position encoders to determine clamp and screw locations. In most cases, the cost to upgrade a newer injection-molding machine is justified by the reduction in part cost.

Parts can also incorporate ribs, bosses, gussets, and through-holes. ICM is particularly suited to relatively flat parts, such as automobile load floors, sunroof liners, seat backs, and door panels.

Another new process is the plastic injection-molding method of forming in which heat-softened material is forced under pressure into a cavity, where it cools and takes the shape of the cavity. The molding operation cannot be completed in one step because details such as screw threads and ribs may be easily integrated into the

mold. High process repeatability is important to economical operation, because it means that few variables must be monitored and adjusted during the process. The key benefit of electric molding technology (EMT) is that it delivers this repeatability, while improving productivity and quality.

Repeatability improvement is the reason that will likely also pull EMT into the mainstream of injection molding. This success is based on the fact that electric machines can control variables much more closely than is possible at comparable costs with hydraulic machinery. This tighter process capability translates into a variety of benefits, including less scrap, lower labor costs, and higher quality.

The essential *repeatability potential* for EMT is inherently higher than that of hydraulic power. The reason for this is that hydraulic drives are typically distributed systems, involving a compressible fluid and a complex network of hoses, tubes, and valves that enable one or two pumps to drive all machine axes. Therefore, any conditions that affect fluid or flow properties also affect positioning of the machine.

By contrast, an electric machine has a motor for each axis. In this case, “axis” may be defined as any motion that is controlled through a feedback loop on the basis of variables such as time, position, pressure, or velocity. On an injection-molding machine, the main linear axes involve clamping, ejection, injection, and sled pull-in. Rotary axes may control extrusion and, in some cases, the height adjustment.

An all-electric power train on one of these axes may consist of a belt, two pulleys, and a ballscrew. With a separate motor for each axis, electric machines have the ability to drive and coordinate all axes of motion simultaneously, a significant advantage over hydraulic machines in some applications. Whatever its configuration, the electromechanical power train is rigid, “solid on solid.”

Currently, EMT is more expensive than hydraulic machines, as is true with most newer technology. However, when comparing prices with hydraulic machines, specifications and capabilities should be balanced. By the time circuits and controls on a hydraulic machine are enhanced to approach to performance of a general-application electric, the cost difference narrows significantly—and hydraulic technology remains less precise.

Because it impacts molding costs in so many ways, hydraulic oil will be seen as a business liability as well as an environmental hazard. Any increase in electricity prices will also drive demand for EMT. In the mold-building industry, a corresponding increase is anticipated in the production of servo-electric systems to actuate core pulls and other functions. The environment of the molding plant will likely change considerably in a relatively few years, along with the standard of quality that is expected from the process.

Ink

Colored liquid or paste for writing, drawing, marking, and printing. Black writing inks usually contain gallotannate of iron that is obtained by adding an infusion of nutgalls to a solution of ferrous sulfate. Good *writing ink* is a clear, filterable solution, not a suspension. It flows easily from the pen without clogging; gives a smooth, varnishlike coating; and adheres to inner fibers of the paper without penetrating through the paper. It must have an intense color that does not bleach out. Ink is essentially a pigment in a liquefying and adhesive medium, but the *iron-gallotannate* writing inks develop their full color by chemical action and become insoluble in the outer fibers of the paper. For the proper development of the black color in gallotannate inks, a high percentage of iron is needed, and this

requires a liberal use of acid, which will tend to injure the paper. It is thus usually the practice to reduce the amount of iron and bring up the color with dyes or pigments. Gums or adhesive materials may also be added.

Carbon inks are composed of lamp black or carbon black in solutions of gums or glutenous materials. *India ink* is a heavy-bodied drawing ink. The original India ink, or *Chinese ink*, was made with a jet-black carbon pigment produced by burning tung oil with insufficient air. The pigment was imported into Europe in compressed sticks known as *indicum*. India ink was originally only black ink, but the name is now used also for colored, heavy drawing inks made with various mineral pigments. *Marking inks* are usually solutions of dyes that are fast to laundering, but they may also be made with silver salts that develop full color and stability by the application of heat. *Fountain-pen ink* is not a special composition ink, but is a writing ink free of sediment and tendency to gum. It usually contains tannic, gallic, and hydrochloric acids with a pH above 2 to avoid corrosion. *Permanent inks* contain dissolved iron, not over 1%, to avoid sludge. *Ballpoint ink* is usually a paste and is a true solution with 40%–50% dye concentration. It must be stable to air, noncorrosive, and a good lubricant. An *encaustic ink* is a special writing ink that will penetrate the fibers of the paper and set chemically to make erasure difficult, but an *indelible ink* for textiles is a marking ink. *Invisible-writing inks*, or *sympathetic inks*, are inks that remain invisible until the writing is brought out by the application of heat or with another chemical that develops the color. They are made with sal ammoniac or salts of metals. *Magnetic ink* for use on bank checks to permit mechanical processing contains 50%–70% of a magnetic powder that is smaller than 197 μm . (5 μm) in particle size. The powder may be hydrogen-reduced iron, carbonyl iron, or electrolytic iron.

Printing inks are in general made with carbon black, lampblack, or other pigment suspended in an oil vehicle, with a resin, solvent, adhesive, and drier. But there are innumerable modifications of printing inks to meet different conditions or printing and varieties of surfaces. The oil or chemical vehicles are innumerable, and the pigments, resin straighteners and gloss formers, adhesives, tackifiers, and driers, vary greatly to suit the nature of surface coating of the base material. Oils may dry by oxidation, polymerization, absorption, or solvent evaporation; and resins may be used to add gloss, strength, hardness, and color fastness or to increase the speed of drying. It is estimated that there are about 8000 variables in an ink, and thus printing ink is a prescription product for any given job. They are not normally purchased on composition specification, but on ability to meet the requirements of the printing.

Inoculant

Materials that, when added to molten metal, modify the structure and thus change the physical and mechanical properties to a degree not explained on the basis of the change in composition resulting from their use. Ferrosilicon-base alloys are commonly used to inoculate gray irons and ductile irons.

Inoculated (Cast) Iron

Cast iron with a fine, evenly dispersed graphite flake structure giving improved mechanical properties compared with a normal gray cast iron. This structure is developed by inoculation, that is, adding a small quantity of finely powdered refractory material, such as calcium silicide, to the molten metal immediately prior to pouring. The powder particles provide many nucleation sites for the

graphite and hence ensure the development of large numbers of fine graphite flakes.

Inoculation

The addition of a material to molten metal to form nuclei for recrystallization. See also *inoculant*.

Inorganic

Being or composed of matter other than hydrocarbons and their derivatives or matter that is not of plant or animal origin. Contrast with *organic*.

Inorganic Pigments

Natural or synthetic metallic oxides, sulfides, and other salts that impart heat and light stability, weathering resistance, color, and migration resistance to plastics.

Inorganic Polymer

An inorganic polymer is defined as a giant molecule linked by covalent bonds but with an absence or near absence of hydrocarbon units in the main molecular backbone; these may be included as pendant side chains. Carbon fibers, graphite, and so forth are considered inorganic polymers. Much of inorganic chemistry is the chemistry of high polymers.

For compounds that do not melt or dissolve without chemical change, both the absence of an equilibrium vapor pressure and the observation of a disassociation pressure resulting from depolymerization bring them into the framework of the definition.

Properties

Some special characteristics of many inorganic polymers are higher Young's modulus and a lower failure strain compared with organic polymers. Relatively few inorganic polymers dissolve in the true sense, or alternatively, if they swell; few can revert. Crystallinity and high glass transition temperatures are also much more common than in organic polymers. In highly cross-linked inorganic polymers, stress relaxation frequently involves bond interchange.

The properties of inorganic polymers require a different technology from that of their organic counterparts. Such technology is either completely new (such as reconstructive processing—the spinning of an inorganic compound on an inorganic support or binder subsequently removed by oxidation/volatilization), or it has been adapted from other fields, for example, glass technology. Thus, reconstructed vermiculite can give flexible sheets. Yarn, paper, woven cloth, and even textiles can be made from alumina and zirconia fibers by the spinning/volatilization process. A mica-forming glass ceramic is resistant to thermal and mechanical shock and can be worked with conventional metalworking tools.

Classification

Inorganic polymers can be classified in a number of ways. Some are based on the composition of the backbone, such as the silicones (Si–O), the phosphazenes (P–N), and polymeric sulfur (S–S). Others are based on their connectivity, that is, the number of network bonds

linking the repeating unit into the network. Thus, the silicones based on R_2SiO , the phosphazenes based on NPX_2 , and polymeric sulfur each have a connection of two, while boric oxide based on B_2O_3 has a connectivity of three, and amorphous silica based on SiO_2 has a connection of four.

Types

The number of inorganic polymers is very large. Sulfur, selenium, and tellurium all form high polymers. Polymers of sulfur are usually elastomeric, and those of selenium and thorium are generally crystalline. In the melt at 220°C , the molecular weight of the sulfur polymer is about 12,000,000 and that of selenium about 800,000.

Silicones

Perhaps the best known of all the synthetic polymers based on inorganic molecular structures are the silicones, which are derived from the basic units.

Chalcogenide Glasses

These are amorphous cross-linked polymers with a connectivity of three. Probably the best known is arsenic sulfide, $(As_2S_3)_n$, which can be used for infrared transparent windows. Threshold and memory switching are also interesting properties of these glasses. Ultraphosphate glasses resemble glassy organic plastics and can be processed by the same methods, such as extrusion and injection molding. They are used for antifouling surfaces for marine applications and in the manufacture of nonmisting spectacle lenses.

Graphite

This is a well-known 2D polymer with lubricating and electrical properties. Intercalation compounds of graphite can have supermetallic anisotropic properties.

Boron Polymers

Structurally related to graphite is hexagonal boron nitride. Like graphite, it has lubricating properties, reflecting the relationship between molecular structure and physical properties, but unlike graphite, it is an electrical insulator. Molybdenum disulfide, $(MoS_2)_n$, with a similar and related structure, is also a solid lubricant. Both graphite and hexagonal boron nitride can be readily machined. Outstanding properties of the latter include high thermal and chemical stability and good dielectric properties. Crucibles and such items as nuts and bolts can be made from this material.

Borate glasses with comparatively low softening points are used as solder and sealing glasses and can be prepared by fusing mixtures of metal oxides with boric oxide, $(B_2O_3)_n$.

Silicate Polymers

The silicates, both crystalline and amorphous, supply a very large number of inorganic polymers. Examples include the naturally occurring fiberlike asbestos and sheetlike mica. The industrially important water-soluble alkali metal silicates can give highly viscous polymeric solutions. Borosilicate glasses form another important group of silicate polymers. The Pyrex type is well known for its resistance to thermal shock; the leached Vycor type is porous and can be used for filtering bacteria and viruses. Asbestos occurs as a ladder polymer, of which crocidolite is the most important, and as layer polymer, exemplified by chrysotile. The zeolites, many of which have been found naturally or have been synthesized, are 3D network polymers. Their uses as molecular sieves are well known.

Other Polymers

Silicon nitride, $(Si_3N_4)_n$, is another macromolecule with interesting properties. Prepared by heating of silicon powder in an atmosphere of nitrogen (nitridation) at above 1200°C , the product is a material that can be machined readily and with good thermal shock resistance and creep resistance at high temperatures, which is further improved by admixture of another inorganic macromolecule silicon carbide, making it useful for applications in gas turbine, diesel engines, thermocouple sheaths, and a variety of components.

Allotropic forms of carbon boron nitride are diamond and cubic boron nitride, both preparable by high-temperature syntheses and characterized by extreme hardness, which make them useful industrially in cutting and grinding tools.

Importance

Inorganic polymeric materials are growing in importance as a result of a combination of two major factors: the depletion of the world's fossil fuel reserves (the basis of the petrochemical industry) and the ever-increasing demands of modern technology, coupled with environmental and health regulations, such as flame retardancy and nonflammability.

Inorganic Zinc-Rich Paint

Coating containing a zinc powder pigment in an *inorganic* vehicle.

Insecticides

Chemicals, either natural or synthetic, used to kill or control insects, particularly agricultural pests. They are also referred to as *pesticides*. Of about 800,000 known species of insects, one-half feed directly on plants, retarding growth of the plant and causing low yields and interior crops. The production of insecticides is now one of the important branches of the chemical industry, and increasing quantities are used; but the specification and use of insecticides require much skill because of the cumulative effect on the earth and animal or plant life. Indiscriminate use may destroy honeybees and other useful insects, produce sterility of soils by killing worms and anaerobic life, and poison the waters of lakes and streams. Dichlorodiphenyltrichloroethane (DDT), for example, is highly valuable for the control of malaria and other insect-borne diseases, but its uncontrolled use as an insecticide has been disastrous to wildlife.

Insecticides are generally classified as *stomach poisons* and *contact poisons*. Stomach poisons include *calcium arsenate*, a white powder, which constitutes about one-half of all insecticides used, and also paris green, lead arsenate, and white arsenic. *Cryolite*, or *sodium fluoroaluminate*, and sodium fluoride are used occasionally. An *antimetabolite* is not a direct poison, but acts on the insect to stop the desire for food so that the insect dies from starvation.

A *larvicide* is a chemical, such as chloropicrin, used to destroy fungi and nematodes in soils and insect eggs and organisms in warehouses. Chemicals used against fungi and bacteria are called *fungicides* and *bactericides*, and those used to control plant diseases caused by viruses are called *viricides*. None of these are properly classified as insecticides, but are often used with them. Herbicides are used to kill weeds, usually by overstimulating cell growth. Most of the pest-control chemicals are cumulative toxic poisons. *Benzene hexachloride* destroys bone marrow, and all the chlorinated hydrocarbons affect the liver. *Deodorants* may have an insect-kill action,

but are usually chemicals such as chlorophyll that combine with impurities in the air to eliminate unpleasant odors.

Insecticides may be solids or liquids, and the solids may be applied as a fine powder, usually in dilution and a dusting powder, or the powder may be suspended in a liquid carrier. Usually, the proportion of poison mixed with a metal powder is no more than 5%. The mineral carrier, or *dusting powder*, for this purpose should be gritless and inert to the insecticide. Ordinary *dusting clay* is a light, fluffy, air-floated kaolin, or it may be a finely ground, soft limestone.

Some materials, such as citronella oil, used as mosquito repellents in households, have little or no value as insecticides for the eradication of mosquitoes in important applications such as at military sites or mining and lumbering camps. The *aerosol bomb* employed during the World War II contained 3% DDT, 2–20 pyrethrum concentrate, 5 cyclohexanone, 5 mineral oil, and the balance a carrier gas. *Dimethyl phthalate*, a liquid, is a mosquito repellent having an effect lasting 1.5 h in the open air.

The insecticide called *DDT* was used effectively during the World War II against flies, mosquitoes, body lice, and agricultural pests. It has no noxious odor, but it is cumulative and in concentration is toxic to humans and other warm-blooded animals. Oil paint containing 0.5%–5% DDT kills flies on walls painted with it. Because it is highly resistant to degradation, DDT is now limited to essential uses.

Insert

A general term referring to small devices or piece of material set into something larger by casting in, pressing, screwing, etc., to fulfill some special local function such as a bearing and screw location.

Insert (Metals)

(1) A part formed from a second material, usually a metal, which is placed in the molds and appears as an integral structural part of the final casting. (2) A removable portion of a die or mold.

Insert (Plastics)

An integral part of a plastic molding consisting of metal or other material that may be molded or preformed to position after the molding is completed.

Insert Die

A relatively small die that contains part or all of the impression of a forging and is fastened to a master die block.

Inserted-Blade Cutters

Cutters having replaceable blades that are either solid or tipped and are usually adjustable.

In Situ—In its Normal Place

In a metallurgical context, this Latin term indicates that the item of interest was examined in its normal location rather than being removed to a laboratory.

Instantaneous Erosion Rate

The slope of a tangent to the cumulative erosion-time curve at a specified point on that curve.

Instantaneous Recovery

The decrease in strain occurring immediately upon unloading a specimen. A more reproducible value is obtained if the decrease in strain is measured after a given small increment of time (such as 1 min) following unloading. The value is expressed in the same units as strain, that is, the decrease in weight divided by the gauge length, usually in inches per inch.

Instantaneous Strain

The strain occurring immediately upon loading a creep specimen. Value is measured after loading to obtain a more reproducible value. The value is expressed in the same units as strain, that is, the extension divided by the gauge length, usually in inches per inch.

Instrument Response Time

The time required for an indicating or detecting device to attain a defined percentage of its steady-state value following an abrupt change in the quantity being measured.

Instrumented Impact Test

An impact test in which the load on the specimen is continually recorded as a function of time and/or specimen deflection prior to fracture.

Insulating Pads and Sleeves

In foundry practice, insulating material, such as gypsum and diatomaceous earth, used to lower the rate of solidification. As sleeves on open risers, they are used to keep the metal liquid, thus increasing the feeding efficiency. Contrast with *chill*.

Insulators

These are any materials that retard the flow of electricity and are used to prevent the passage or escape of electric current from conductors. No materials are absolute nonconductors; those rating lowest on the scale of conductivity are therefore the best insulators. An important requirement of a good insulator is that it does not absorb moisture, which would lower its resistivity. Glass and porcelain are the most common line insulators because of low cost. Pure silica glass has an average dielectric strength of 20×10^6 V/m and glass-bonded mica about 17.7×10^6 V/m, while ordinary porcelain maybe as low as 8×10^6 V/m and steatite about 9.4×10^6 V/m. Slate, steatite, and stone slabs are still used for panel boards, but there is now a great variety of insulating boards made by compressing glass fibers, quartz, or minerals with binders, or standard laminated plastics of good dielectric strength may be used.

Synthetic rubbers and plastics have now replaced natural rubber for wire insulation, but some aluminum conductors are insulated only with an anodized coating of aluminum oxide. Wires to be coated with an organic insulator may first be treated with hydrogen fluoride, giving a coating of copper fluoride on copper wire and aluminum fluoride on aluminum wire.

Integral Composite Structure

Composite structure in which several structural elements, which would conventionally be assembled together by bonding or

mechanical fasteners after separate fabrication, are instead laid up and cured as a single, complex, continuous structure. The term is sometimes applied more loosely to any composite structure not assembled by mechanical fasteners. Or some parts of the assembly may be cocured.

Integral Skin Foam

Urethane foam with a cellular core structure and a relatively smooth skin.

Integrated Circuit

An interconnected array of active and passive elements integrated with a single semiconductor substrate or deposited on the substrate by a continuous series of compatible processes and capable of performing at least one complete electronic circuit function.

Integrated circuits, based on gallium arsenide (GaAs), have come into increasing use since the late 1970s. The major advantage of these circuits is their fast switching speed.

Gallium Arsenide FET

The gallium arsenide field effect transistor (GaAs FET) is a majority carrier device in which the cross-sectional area of the conducting path of the carriers is varied by the potential applied to the gate. Unlike the MOSFET, the gate of the GaAs FET is a Schottky barrier composed of metal and gallium arsenide.

As noted earlier, the major advantage of gallium arsenide integrated circuits over silicon integrated circuits is the faster switching speed of the logic gate. The reason for the improvement of the switching speed of GaAs FETs with short gate lengths (less than 1 μm) over silicon FETs of comparable size has been the subject of controversy. In essence, the speed or gain-bandwidth product of a FET is determined by the velocity with which the electrons pass under the gate. The saturated drift velocity of electrons in gallium arsenide is twice that of electrons in silicon; therefore, the switching speed of gallium arsenide might be expected to be only twice as fast.

Intelligent Materials

See *smart materials*.

Intense Quenching

Quenching in which the quenching medium is cooling the part at a rate of at least $2\frac{1}{2}$ times faster than still water. See also *Grossmann number*.

Intensiostatic

See *galvanostatic*.

Intensity

The energy per unit area per unit time incident on a surface.

Intensity Ratio

The ratio of two (relative) intensities.

Intensity of Scattering

The energy per unit time per unit area of the general radiation diffracted by matter. Its value depends on the scattering power of the individual atoms of the material, the scattering angle, and the wavelength of the radiation.

Intensity, x-Rays

The energy per unit of time of a beam per unit area perpendicular to the direction of propagation.

Interatomic Bonding

The manner in which atoms bond together. In electrovalent bonding, also termed ionic or heteropolar bonding, an element, typically a metal, having a small number of valence electrons combines with one having a large number, typically a nonmetal. For example, sodium as a single valence electron in its outer shell and eight electrons in its full second shell. Chlorine has seven valence electrons in its outer shell. When these two elements combine, a sodium atom donates the single valence electron in its outer shell to the outer shell of a chlorine atom. Both atoms then have full, and hence stable, outer shells. The atoms, respectively, depleted an increased buy-in electron, and their associated charge is termed ions, represented as Cl^{-1} and Na^{+1} . These opposite electrostatic charges powerfully attract forming a strong bond for the solid compound. In a solution, ionically bonded materials can ionize allowing the two ions to move independently within the solution. Such movement is the phenomenon underlying *electrochemistry*. In covalent bonding, also termed homopolar bonding, the atoms share electrons to fill their outer shells to form fairly stable molecules. A simple example is hydrogen with its single valence electron; molecules of hydrogen are formed by two atoms each contributing its electron to a shared outer shell filled with two electrons. Coordinate or dative covalent bonding is a variation in which the bond is formed by the sharing of a pair of electrons donated from one of the atoms. In metallic bonding, the valence electrons of all the atoms are pooled, effectively forming a cloud shared between the mass of atoms; see *band theory*. Apart from these relatively powerful bonds that hold atoms together, there are lesser secondary forces capable of holding molecules together. These are termed *van der Waals forces*.

Intercalation Compounds

These are crystalline or partially crystalline solids consisting of a host lattice containing voids into which guest atoms or molecules are inserted. Candidate hosts for intercalation reactions may be classified by the number of directions (0–3) along which the lattice is strongly bonded and thus unaffected by the intercalation reaction. Isotropic, 3D lattices (including many oxides and zeolites) contain large voids that can accept multiple guest atoms or molecules. Layer-type, 2D lattices (graphite and clays) swell up perpendicular to the layers when the guest atoms enter. The chains in 1D structures (polymers such as polyacetylene) rotate cooperatively about their axes during the intercalation reaction to form channels that are occupied by the guest atoms.

Properties

The physical properties of the host are often dramatically altered by intercalation. In carbon-based hosts such as graphite, polyacetylene,

and solid C_{60} , the charge donated to the host by the guest is delocalized in at least one direction, leading to large enhancements and electrical conductivity. Some hosts can be intercalated by electrodonating or electron-accepting guests, leading, respectively, to *n*-type or *p*-type synthetic metals, analogous to doped semiconductors. The chemical bonding between guest and host can be exploited to fine-tune the chemical reactivity of the guest. In many cases, superconductors can be created out of nonsuperconducting constituents.

Applications

Many applications of intercalation compounds derive from the reversibility of the intercalation reaction. The best-known example is pottery. Water intercalated between the silicate sheets makes wet clay plastic, while driving the water out during firing results in a dense, hard, durable material. Many intercalation compounds are good ionic conductors and are thus useful as electrodes in batteries and fuel cells. A technology for lightweight rechargeable batteries employs lithium ions, which shuttle back and forth between two different intercalation electrodes as the battery is charged and discharged: vanadium oxide (3D) and graphite (2D). Zeolites containing metal atoms remain sufficiently porous to serve as catalysts for gas-phase reactions. Many compounds can be used as convenient storage media, releasing the gas molecules in a controlled manner by mild heating.

Intercept Method

Techniques for measuring microstructural features. A line is projected across the structure, and the intercept points at which it crosses the various phase boundaries are noted. The distance between intercepts is totaled for each phase to give a ratio of the volumes of the phases. Alternatively, the number of features, such as grain boundaries or inclusions, that intercept the line may be recorded to allow calculation of grain size or the quantity of inclusions.

Intercommunicating Porosity

See preferred term *interconnected porosity*.

Interconnected Pore Volume

The volume fraction of all pores that are interconnected within the entire pore system of a powder compact or sintered product.

Interconnected Porosity

A network of connecting pores in a sintered object that permits a fluid or gas to pass through the object. Also referred to as interlocking or open porosity.

Intercritical Annealing

Any annealing treatment that involves heating to, and holding at, a temperature between the upper and lower critical temperatures to obtain partial austenitization, followed by either slow cooling or holding at a temperature below the lower critical temperature.

Intercrystalline

Any feature at the interface between the crystals, or grains, of a polycrystalline material.

Intercrystalline Corrosion

See *intergranular corrosion*.

Intercrystalline Cracking

See *intergranular cracking*.

Interdendritic

Occurring or located at the boundaries between dendrites.

Interdendritic Corrosion

Corrosive attack that progresses preferentially along interdendritic paths. This type of attack results from local differences in composition, such as coring commonly encountered in alloy castings.

Interdendritic Porosity

Voids occurring between the dendrites in cast metal.

Interface

The boundary between any two phases. Among the three phases (gas, liquid, and solid), there are five types of interfaces: gas–liquid, gas–solid, liquid–liquid, liquid–solid, and solid–solid.

Interface (Composites)

The boundary or surface between two different, physically distinguishable media. With fibers, the contact area between the fibers and the sizing or finish. In a laminate, the contact area between the reinforcement and the laminating resin.

Interface Activity

A measure of the chemical potential between the contacting surfaces of two particles in a compact or two grains in a sintered body.

Interface of Phases

The abrupt transition from one phase to another at the boundaries of gas, liquid, and solid even though subject to the kinetic effects of molecular motion, is statistically a surface only one or two molecules thick.

A unique property of the surfaces of the phases that adjoin at an interface is the surface energy that is the result of unbalanced molecular fields existing at the surfaces of the two phases. Within the bulk of a given phase, the intermolecular forces are uniform because each molecule enjoys a statistically homogeneous field produced by neighboring molecules of the same substance. Molecules in the surface of a phase, however, are bounded on one side by an entirely different environment, with the result that there are intermolecular forces that then tend to pull the surface molecules toward the bulk of the phase. A drop of water, as a result, tends to assume a spherical shape to reduce the surface area of the droplet to a minimum.

Interfacial Tension

The contractile force of an interface between two phases.

Interference

The difference in lateral dimensions at room temperature between two mating components before assembly by expansion, shrinking, or press fitting. Can be expressed in absolute or in relative terms.

Interference

In light, and other energy forms transmitted as a waveform, the alternate light and dark bands that result when two transmissions meet with the waves out of phase.

Interference Filter

A combination of several thin optical films to form a layered coating for transmitting or reflecting a narrow band of wavelengths by interference effects.

Interference Fit

(1) A joint or mating of two parts in which the male part has an external dimension larger than the internal dimension of the mating female part. Distension of the female by the male creates a stress, which supplies the bonding force for the joint. (2) Any of the various classes of fit between mating parts where there is nominally a negative or zero allowance between the parts and where there is either part interference or no gap when the mating parts are made to the respective extremes of individual tolerances that ensure the tightest fit between the parts. Contrast with *clearance fit*. (3) A joint in which one component fits inside and is slightly larger than the receiving orifice and the other. They may be simply pushed together—a force fit—or the outer may be heated (and/or but less common, the inner cooled) to allow the inner to be inserted easily—a shrink fit. A typical shrink fit interference would be a difference in dimensions of one in one thousand. Less common, and less reliable, is the wrong fit in which the interfaces are slightly tapered and the components are rotated relative to each other as they are pushed together. They are then held together by a combination of interference and galling.

Interference Techniques

Techniques of microscopical examination that utilize a single beam of light that is split into two, one of which is reflected onto the surface being examined and the other onto a high-quality reference surface. The return beams from the two surfaces are then recombined so that any irregularities on the surface being examined are revealed by interference patterns.

Interference of Waves

The process whereby two or more waves of the same frequency or wavelength are combined to form a wave with amplitude that is the sum of the amplitudes of the interfering waves.

Interferometer

An instrument in which the light from a source is split into two or more beams, which are subsequently reunited and interfered after traveling over different paths.

Intergranular

Occurring or located at the interface between crystals or grains. Also called intercrystalline. Contrast with *transgranular*.

Intergranular Beta

In titanium alloys, β phase situated between α grains. It may be at grain corners, as in the case of equiaxed α -type microstructures in alloys having low β -stabilizer contents.

Intergranular Corrosion

Corrosion occurring preferentially at grain boundaries, usually with slight or negligible attack on the adjacent grains. See also *interdendritic corrosion*.

Intergranular Cracking

Cracking or fracturing that occurs between the grains or crystals in a polycrystalline aggregate. Also called intercrystalline cracking. Contrast with *transgranular cracking*.

Intergranular Fracture

Brittle fracture of a polycrystalline material in which the fracture is between the grains, or crystals, that form the material. Also called intercrystalline fracture. Contrast with *transgranular fracture*.

Intergranular Penetration

In welding, the penetration of a filler metal along the grain boundaries of a base metal.

Intergranular Stress-Corrosion Cracking

Stress-corrosion cracking in which the cracking occurs along grain boundaries.

Interlaminar

Between two adjacent laminae, for example, an object (such as a flaw), an event (such as a fracture), or a potential field (such as shear stress). See also *fracture* (composites).

Interlaminar Shear

Shearing force tending to produce a relative displacement between two laminae in a laminate along the plane of their interface.

Intermediate Annealing

Annealing wrought metals at one or more stages during manufacture and before final treatment.

Intermediate Electrode

Same as *bipolar electrode*.

Intermediate Flux

A soldering flux with a residue that generally does not attack the base metal. The original composition may be corrosive.

Intermediate Heat Treatment/Annealing

Heat treatment carried out between stages of cold working.

Intermediate Phase

In an alloy or a chemical system, a distinguishable homogeneous phase with composition range that does not extend to any of the pure components of the system.

Intermediate-Temperature Setting Adhesive

An adhesive that sets in the temperature range from 30°C to 100°C (87°F–211°F).

Intermetallic Compounds

Intermetallic compounds are materials composed of two or more types of metal atoms, which exist as homogeneous, composite substances and differ discontinuously in structure from that of the constituent metals. They are also called, preferably, intermetallic phases. Their properties cannot be transformed continuously into those of their constituents by changes of composition alone, and they form distinct crystalline species separated by phase boundaries from their metallic components and mixed crystals of these components. It is generally not possible to establish formulas for intermetallic compounds on the sole basis of analytical data, so formulas are determined in conjunction with crystallographic structural information.

The term *alloy* is generally applied to any homogeneous molten mixture of two or more metals, as well as to the solid material that crystallizes from such a homogeneous liquid phase. Alloys may also be formed from solid-state reactions. In the liquid phase, alloys are essentially solutions of metals in one another, although liquid compounds may also be present. Alloys containing mercury are usually referred to as amalgams. Solid alloys may vary greatly in range of composition, structure, properties, and behavior.

Phase Transformations

Much of the accumulated experimental information about the nature of the interaction and the phase transformation in systems composed of two or more metals is contained in phase or equilibrium diagrams. For example, in the phase relationships in the copper–zinc (brass) system, such phase diagrams, even for binary metal systems, may be of all degrees of complexity, ranging from systems showing the formation of simple solid solutions to dozens of intermetallic phases exhibiting structural (polymorphic), order–disorder, magnetic, or bond-type or deformation-type transformations as a function of composition or temperature, or both. Intermetallic compounds are composed of two or more metals. They may be stable over only a very narrow or over a relatively wide range of composition, which may be stoichiometric, as for the compounds GaAs, PdCu₁₃, Zr₅₇Al₄₃, and Nb₄₈Ni₃₉Al₁₃, or non-stoichiometric, as for the compounds Co_{1-x}Te_x (where x extends continuously from 0.5 to 0.67) and Al_{0.08}Ge_{0.2}Nb₃ (an important superconducting alloy).

Crystal Structure

The crystal structures found for intermetallic compounds may likewise range from the simple rock-salt structure displayed by BeTe to the extremely complex arrangement found for NaCd₂, Mg₃₂(Al,Zn)₄₉, and Cu₄Cd₃.

Family Groups

The intermetallic compound families include the borides, hydrides, nitrides, silicides, and aluminides of the transition metal elements of groups V and VI in the periodic table combined with semimetallic elements of small diameter. More than 1000 possible compounds fit this definition, with approximately 200 of them having melting points above 1500°C.

Methods of preparation for silicides and aluminides are very similar to those used for carbides, nitrides, and borides: (1) synthesis by fusion or sintering, (2) reduction of the metal oxide by silicon or aluminum, (3) reaction of the metal oxide with SiO₂ and carbon, (4) reaction of the metal with silica and halide, or (5) fused salt electrolysis. The simplest preparation method consists of mixing the metal powders in proper ratio and then heating the mixture in vacuum or inert atmosphere to the temperature where reaction begins. At that point, the exothermic reaction furnishes the heat needed to drive it to completion.

The best forming methods are hot pressing and vacuum sintering. Some intermetallic compounds—ZrB₄ with MoSi₂, Mo₂NiB₂, and Mo₂CoB, for example—are as hard as tungsten carbide. Borides of zirconium or titanium added in small amounts to Al₂O₃, BeO, ZrO₂, or ThO₂ improve their resistance to heat checking. Nitrides of aluminum, titanium, silicon, and boron are used as refractory materials.

Fibers and whiskers of intermetallic materials also are being considered for strength-enhancing fillers in metal- and ceramic-matrix composites.

Intermetallic Materials

Ordered intermetallics bridge the gap between metals and ceramics. They exhibit physical properties characteristic of metals and can be processed by conventional casting techniques, but their mechanical properties resemble those of ceramics. Some intermetallics also have poor resistance to oxidation and sulfidation attacks at elevated temperatures.

The primary barrier to their use in load-carrying applications is their brittleness or low crack tolerance. The reasons for this behavior include complex crystal structure and deformation behavior, embrittlement due to defects (interstitials, vacancies) and to hydrogen, and notch sensitivity. The major effort in research and development on intermetallics is concerned with increasing the ductility and toughness while maintaining good high-temperature strength, stiffness, creep resistance, and resistance to oxidation and sulfidation.

Ordered Structures

An ordered intermetallic is an alloy of two elements, A and B, in specific ratios (e.g., AB, AB₂, AB₃, A₂B, A₃B). In the fully ordered condition, the two species are arranged on specific lattice sites. Depending on their constitution, ordered intermetallics are divided into groups such as aluminides, silicides, and beryllides.

Nickel Aluminides

The two major nickel aluminides are Ni_3Al and NiAl .

In the crystal structure of Ni_3Al , the nickel atoms occupy the face-centered sites, and the aluminum atoms occupy the corner sites of a face-centered cubic unit cell. Ni_3Al has excellent elevated-temperature strength and good oxidation resistance; there is an anomaly in the yield strength in that it increases, rather than decreases (as is the case with most other structural materials), with increasing temperature. Single crystals of Ni_3Al are highly ductile, whereas polycrystalline materials are brittle at ambient temperatures because of the brittleness of the grain boundaries. Polycrystalline Ni_3Al is also prone to environmental embrittlement at both ambient and elevated temperatures.

The mechanical properties of Ni_3Al can be improved by alloying additions of boron, chromium, hafnium, molybdenum, and zirconium. Binary Ni_3Al alloys are being examined for alternative applications, such as turbocharger rotors and diesel engine trucks.

The alloy NiAl has two-thirds the density of nickel-base superalloys and, in addition, exhibits significantly higher (four to eight times depending on composition and temperature) thermal conductivity and excellent oxidation resistance. Although binary NiAl is brittle even in single-crystal form, minor alloying with iron, molybdenum, and gallium has recently been shown to significantly improve tensile ductility.

Iron Aluminides

The two major iron aluminides are Fe_3Al and FeAl . Both have excellent oxidation resistance and corrosion resistance because they form protective scales at elevated temperatures in hostile environments. They also are low in cost and have low density and good strength of two intermediate temperatures. Their main drawbacks are poor ductility and brittle fracture at ambient temperatures and poor strength and creep resistance above 650°C . The poor ductility at ambient temperatures is caused by the environmental embrittlement due to hydrogen from the moisture in the air. These compounds are being investigated as potential replacements for stainless steel in selected applications in the chemical, petroleum, and coal industries.

Titanium Aluminides

The major titanium aluminides are Ti_3Al and TiAl . They are well suited for aerospace applications because of their low density compared to the standard engine materials, nickel-base superalloys. The density of titanium aluminides is about half that of superalloys. Titanium aluminides also have good high-temperature strength but poor ductility and toughness at ambient temperatures.

Alloys corresponding to Ti_3Al have been developed as two-phase alloys with compositions based on titanium with 23%–25% aluminum and 10%–30% niobium (a phase is a constituent of an alloy that is physically distinct and is homogeneous and chemical composition). The oxygen impurity level is a very important consideration, because it has a large effect on the ductility. Ti_3Al has limited ductility at ambient temperatures. The mechanical properties depend on the composition and the microstructure. Increasing the niobium content increases the ductility, but the toughness and creep resistance remain low. Increasing the aluminum content increases the strength. The microstructure can be altered significantly by thermal mechanical processing.

Promising materials corresponding to TiAl have the following compositions: titanium with 46%–52% aluminum and 1%–10% M, where M is at least one element from the group of metals chromium, molybdenum, niobium, tantalum, vanadium, and tungsten. The

materials are produced as either single-phase or two-phase materials. The two-phase materials contained both the Ti_3Al and the TiAl phases. Additions of niobium or tantalum increase the strength and oxidation resistance of single-phase materials.

The mechanical properties of these alloys are sensitive to these microstructural modifications. Unlike the NiAl alloys, TiAl alloys are produced in the polycrystalline form, and investment casting appears to be the preferred route to producing net-shape components.

A number of gas-turbine engine components have been identified for TiAl -base alloy applications, rotational and stationary compressor components such as high-pressure compressor blades, turbine components such as low-pressure turbine blades, combustor components such as diffuser case and swirler, and nozzle components such as flaps and outer skins. A low-pressure turbine wheel with cast TiAl -base alloy blades has passed a rigorous simulated engine test.

Molybdenum Disilicide

High-temperature silicides are a new class of materials with potential applications in the temperature range 1200°C – 1600°C . However, there are several issues to be solved before they can be used as structural materials. Such issues include (1) improving the intermediate-temperature oxidation behavior to avoid pesting (the disintegration of a silicide material in the oxygen-bearing environment, generally occurring between 300°C and 900°C), (2) increasing the ambient-temperature ductility and toughness, and (3) improving the high-temperature creep resistance. The silicide that seems most promising is molybdenum disilicide (MoSi_2) because of its high melting temperature (2200°C) and excellent oxidation resistance. It has a tetragonal crystal structure. A major problem is its absence of ductility at temperatures up to 1000°C . It also has poor high-temperature strength due to the presence of a grain-boundary silicon-rich phase that may become viscous at very high temperatures. Recent research has shown that this problem may be solved by the addition of carbon into the material.

Production

The primary processing methods for production of intermetallics are melting, casting, ingot processing, and powder metallurgy. The secondary processes include forming, machining, and chemical milling.

Primary Processing

The two major methods of producing intermetallics are by melting and casting or by the production of powders. In the melting of aluminides, the large difference between the melting temperature of aluminum and that of iron, nickel, and titanium must be considered. Other pertinent factors are (1) the large amount of aluminum in the intermetallic, (2) the melting temperature of the intermetallic (it may be higher than that of either constituent), and (3) the general reactivity of the elements to be melted. Similar issues exist for MoSi_2 , except that the difference in the melting temperatures of the elements is smaller.

The melting methods used are air induction melting, vacuum induction melting (VIM), vacuum arc remelting (VAR), vacuum arc double electrode remelting (VADER), electroslag remelting (ESR), plasma melting, and electron-beam melting. Ni_3Al and the iron aluminides can be melted in air, although the high amount of aluminum promotes the rapid formation of a continuous aluminum oxide film on the top of the molten materials. For many applications, it is best to use processes that do not involve air melting, such as VIM, VAR,

VADER, and ESR. The extreme reactivity of molten titanium with moisture and with oxidizing and carburizing environments makes the melting of titanium aluminides in conventional melting crucibles impossible. Titanium aluminides are melted by a process known as the induction skull method, which combines features of consumable arc melting and conventional ceramic crucible induction melting. Also, the VAR process and plasma arc cold hearth melting process have been used to melt titanium aluminides as well as MoSi_2 . Many applications of intermetallics require cast components. Casting methods include sand, investment, centrifugal, directional solidification, and near-net-shape methods.

Finer-grained wrought products are required in other applications. The commercial use of intermetallics at competitive cost requires fabrication by conventional hot-working operations. The primary processing of cast ingots is feasible, but the requirement for hot working is more stringent than for commercial metallic alloys. The secondary processing of intermetallics is very difficult and varies from intermetallic to intermetallic.

Powder metallurgy offers the most flexibility in producing intermetallics. The problem of using powder metallurgy for this purpose is that these production methods often result in surface contamination of the powders. Each of the powder consolidation methods for producing intermetallics from powders has processing difficulties. These methods are hot pressing, hot isostatic pressing, powder injection molding, extrusion, and explosive compaction. The reaction synthesis process has been uniquely applicable for intermetallics and has been used to produce many different materials.

Secondary Processing

Secondary steps such as machining and joining are critical in using these advanced materials for various applications, and extensive efforts have been used to develop these technologies. Innovative joining techniques such as friction welding, capacitor discharge welding, flash welding, laser welding, welding using the combustion synthesis concept, welding using microwaves and infrared waves, electron-beam welding, brazing, and diffusion bonding have been evaluated. A variety of machining techniques including electrodischarge machining, water-jet cutting, ultrasonic machining, and laser cutting are available to precision-machined complex geometries and contours. Conventional grinding, diamond drilling, and boring techniques have seen limited applications in machining TiAl alloys.

Intermetallic Phases

Compounds, or intermediate solid solutions, containing two or more metals, which usually have compositions, characteristic properties, and crystal structures different from those of the pure components of the system.

Intermetallic Matrix Composites (IMCs)

IMCs have recently received considerable attention, and a variety of matrices and reinforcements have been examined to date. Reinforcement type, volume fraction, size, shape, and distribution have been shown to affect microstructure and mechanical properties. Several innovative approaches ranging from conventional techniques, such as mechanical alloying, to more exotic techniques, such as reactive consolidation and magnetron sputtering, have been used to produce these composites.

Significant advances in characterization have been made and continuously reinforced—based alloys (SiC fibers in Ti_3Al + Nb alloys) and particulate-reinforced TiAl alloys (TiAl + TiB_2 particulates), in directionally solidified eutectic's of NiAl, and in discontinuously reinforced MoSi_2 .

Intermittent Weld

A joint formed, deliberately or otherwise, by series of longitudinal welds with gaps between. Where such a weld is deliberate, a chain intermittent weld has the welds on one side aligned with the welds on the other and a staggered intermittent weld has the gaps on one side aligned with the welds on the other.

Internal Friction

The ability of the material to absorb vibration-induced strain energy and dissipate it internally as heat. Similar to *damping capacity*. The conversion of energy into heat via materials subjected to fluctuating stress.

Internal Grinding

Grinding an internal surface such as that inside a cylinder or hole. See also the term *grinding*.

Internal Oxidation

The oxidation of parent material or other phases within the body of the component due to diffusion of oxygen from the exterior. The effect is usually damaging but it may be deliberately induced to produce large quantities of fine oxide particles having a dispersion hardening effect. Also called *subscale formation*.

Internal Shrinkage

A void or network of voids within a casting caused by inadequate feeding of that section during solidification.

Internal Shrinkage Cracks

Longitudinal cracks in a composite pultrusion that are found within sections of roving reinforcement. This condition is caused by shrinkage strains during cure that show up in the roving portion of the pultrusion, where transverse strength is low.

Internal Standard

In spectroscopy, a material present in or added to samples that serves as an intensity reference for measurements, used to compensate for variations in sample excitation and photographic processing in emission spectroscopy.

Internal Standard Line

In spectroscopy, a spectral line of an *internal standard*, with which the radiant energy of an analytical line is compared.

Internal Stress

See preferred term *residual stress*.

International Annealed Copper Standard (IACS)

A measure of electrical resistance and its reciprocal, conductivity. The standard defines pure annealed copper as having, at 20°C, a specific resistance of 1.7241 $\mu\Omega$ -cm and thus a conductivity of 0.58001 reciprocal $\mu\Omega$ -cm. This conductivity is then defined as 100% IACS as the basis for all other metals. As examples, pure annealed silver would have an IACS of 105% and a cold worked cadmium copper an IACS of 85%.

International Screw Thread

An internationally agreed system of screw threads of standard profile with a radiused root and a truncated crest and dimensions in millimeters.

Interpass Temperature

In a multiple-pass weld, the temperature (minimum or maximum as specified) of the deposited weld metal before the next pass is started.

Interphase

The boundary region between a bulk resin or polymer and an adherend in which the polymer has a high degree of orientation to the adherend on a molecular basis. It plays a major role in the load transfer process between the bulk of the adhesive and the adherend or the fiber and the laminate matrix resin.

Interplanar Distance

The perpendicular distance between adjacent parallel lattice planes.

Interply Hybrid

A reinforced plastic laminate in which adjacent laminae are composed of different materials.

Interpulse Time (Resistance Welding)

The time between successive pulses of current within the same impulse.

Interrupted Aging

Aging at two or more temperatures, by steps, and cooling to room temperature after each step. See also *aging*, and compare with *progressive aging* and *step aging*.

Interrupted-Current Plating

Plating in which the flow of current is discontinued for periodic short intervals to decrease anode polarization and elevate the *critical current density*. It is most commonly used in cyanide copper plating.

Interrupted Quenching

A quenching procedure in which the workpiece is removed from the first quench at a temperature substantially higher than that of the quenchant and is then subjected to a second quenching system having a different cooling rate than the first.

Intersection Scarp

A line, of any shape, that is the locus of intersection of two portions of a crack with one another. This is exemplified by intersection of a portion of a slow crack running wet with a portion not wetted. See also *transition scarp*.

Interstice

Generally, any gap situated between two features. More specifically, in a metallurgical context, the space between the atoms forming the main crystal lattice.

Interstitial

The space, or an atom located in the space, between the atoms forming the main crystal lattice. Interstitial atoms are much smaller than the primary atoms, for example, carbon and nitrogen are interstitials in iron. See *solution*.

Interstitial Solid Solution

A type of solid solution that sometimes forms in alloy systems having two elements of widely different atomic sizes. Elements of small atomic size, such as carbon, hydrogen, and nitrogen, often dissolve in solid metals to form this solid solution. The space lattice is similar to that of the pure metal, and the atoms of carbon, hydrogen, and nitrogen occupy the spaces or interstices between the metal atoms.

Intersystem Crossing

A transition between electronic states that differ in total spin quantum number.

Interval Erosion Rate

The slope of a line connecting two specified points on the cumulative erosion-time curve.

Internal Estimate

The estimate of a parameter given by two statistics, defining the endpoints of an interval.

Interval Test

Method used to test heat extraction rates of various quenchants. This test measures the increase in temperature of a quenchant when a standard bar of metal is quenched for 5 s. Faster quenchants will exhibit greater temperature increases.

Intracrystalline

Within or across the crystals or grains of a metal; same as transcrystalline and transgranular.

Intracrystalline Cracking

See *transgranular cracking*.

Intragranular

Any effect such as precipitation occurring within individual grains. Not to be confused with intergranular (between grains) or transgranular (across grains).

Intralaminar

Within a single lamina, for example, an object (such as a void), an event (such as a fracture), or a potential field (such as a temperature gradient). See also the term *interlaminar*.

Intraply Hybrid

A reinforced plastic laminate in which more than one material is used within a specific layer.

Intrinsic Viscosity

For a polymer, the limiting value of infinite dilution of the ratio of the specific viscosity of the polymer solution to its concentration in moles per liter.

Introfaction

The change in fluidity and wetting properties of a polymeric impregnating material, produced by the addition of an *introfier*.

Introfier

A chemical that converts a colloidal solution into a molecular one. See also *introfaction*.

Intrusion

Surface notches and steps formed by local slip during fatigue.

Intumescence

The swelling or bubbling of the coating usually because of heating (term currently used in space and fire protection applications).

Invar

An alloy of iron with 36% nickel that has a very low thermal expansion over a range of temperature from about ambient to about 140°C.

Inverse Chill

The condition in a casting section in which the interior is mottled or white, while the other sections are gray iron. Also known as reverse chill, internal chill, and inverted chill.

Inverse Rate Cooling Curve

A graph plotting temperature on the vertical scale against time taken for incremental falls or rises in temperature (e.g., 1 degree intervals) on the horizontal scale. Such graphs are plotted for metals being heated or cooled, and inflections in the curve indicate the temperature of critical points such as phase changes.

Inverse Segregation

Segregation where, contrary to normal, an excess of the lower melting point metal is located at the outer surface of a casting.

Inverted Microscope

A microscope arranged so that the line of sight is directed upward through the objective to the object.

Inverted “V” Segregation

See *segregation*.

Investing

In *investment casting*, the process of pouring the investment slurry into a flask surrounding the pattern to form the mold.

Investment

A flowable mixture, or slurry, of a graded refractory filler, a binder, and a liquid vehicle that, when poured around the patterns, conforms to their shape and subsequently sets hard to form the investment mold.

Investment Casting

(1) Casting metal into a mold produced by surrounding, or *investing*, an expendable pattern with a refractory slurry coating that sets at room temperature, after which the wax or plastic pattern is removed through the use of heat prior to filling the mold with liquid metal. Also called *precision casting* or *lost wax process*. (2) A part made by the investment casting process.

Investment Castings

The investment-casting process derives its name from one operation of the overall process, that of investing, enclosing, or encasing a disposable pattern or pattern cluster within a refractory slurry that subsequently hardens to form a mold. This method of mold making and casting in a hot mold (871°C–1038°C) distinguishes investment casting from other casting procedures. Other casting processes, such as sand casting, die casting, and shell mold casting, employ a split mold-making technique.

The investment-casting process is also known as the lost-wax or precision casting process. (Another technique akin to it is the frozen mercury process.) Investment castings are now used in many industries.

General Description

Investment casting consists of three major operations—pattern production, mold production, and casting:

1. Castings are produced by using disposable patterns. Patterns are formed of wax or plastic by injecting these materials, which are fluid, into a die cavity or cavities. The shape and detail of the part intended for reproduction are cast or machined into the die.

A pattern die is constructed in two parts so that the pattern, or in the case of a multiple-cavity die patterns,

can be removed. Machined-pattern dies may be cut from a solid piece of steel or may be built in components for assembly. Cast pattern dies require that a metal master pattern first be introduced, which is in turn used to cast a soft metal die cavity or cavities. These dies are usually cast from a low-melting alloy such as tin–bismuth. Steel dies are normally used for injection of plastics. In many instances, a part of the foundry gating system (e.g., feeders and runners) is built into the die cavity to eliminate subsequent assembly work in making up a pattern cluster. A pattern die can be made to produce a single pattern, multiple patterns, or only a portion of a pattern of a given part. In the latter case, more than one die would be used and these components would be put together to make a complete pattern.

After the patterns are produced, the next step is making the pattern assembly or pattern cluster with subsequently forming the mold cavity. The pattern assembly consists of the part pattern or patterns and the gating system, which includes feeders, runners, and metal reservoir.

2. The first operation in mold making is to dip the pattern cluster into a liquid mix of silica flour to wet the patterns and then cover them with a dry mix of flour and sand. This forms the dip coat of the patterns and is the start of the mold buildup. There are now two major methods of completing the molds.

The first method is to seal the pattern cluster to a mold board and place a container on the board that encloses the pattern cluster. A refractory slurry is poured into the container, which invests (encloses) the pattern cluster except at that area at the bottom of the mold board where the pattern cluster is stuck to the board. The fluids in the slurry harden chemically and the result is a very dense, hard, heat-resistant mold with the pattern cluster embedded. The mold board is then removed, exposing the end of wax pattern clusters.

An alternative method of completing the mold after the initial dip coating is to continue with the procedure of alternately dipping in a heavier slurry and coating with dry refractory particles until a ceramic shell is formed around the pattern cluster. Drying is necessary between cycles and the number of cycles depends on the strength requirements to contain the molten metal when poured into the mold.

3. The casting operation includes three steps: (1) removing the pattern cluster from the mold, (2) heating the metal to a molten state and pouring it into the mold, and (3) cooling the mold and removing the cast parts from it. The pattern material (wax or plastic) is removed from the mold by a combination of melting and burning. Approximately an 8 h heating cycle at temperatures of about 871°C–1038°C is used to fire the ceramic mold and remove the pattern material.

This, then, leaves a cavity in the mold. The molds are removed from the furnace shortly before casting so they are near furnace temperature when poured.

Depending on the alloy from which the castings are to be made, various melting–casting techniques are used. Alloys are melted while exposed to normal atmosphere, while covered protectively by an inert gas or while the melting crucible and mold are in a vacuum chamber. Melting is usually accomplished by indirect

arc or induction heating. Molds may be cast by “floor pouring” to fill the mold directly from the furnace or from furnace to ladle to mold. The floor-pouring method is used primarily for large molds. The more prevalent way is to secure the mold on top of the melting furnace and invert both furnace and mold so that the alloy enters directly into the mold from the crucible, normally under slight pressure.

After solidification and cooling have taken place, the mold material is mechanically or hydraulically broken away from the castings. The gates are cut from the casting and the casting is processed through other operations of finishing and inspection as required.

Materials

The majority of the alloys cast by this process are iron-, nickel-, or cobalt-base alloys. The iron-base alloys include the complete range from plain carbon steels to the stainless and high-alloy steels. Many nonferrous alloys can also be used, such as gold, brasses, and bronzes, as well as gold, aluminum, and copper alloys.

The alloy to be cast is generally not considered as a restriction, because the process is sufficiently versatile to accommodate almost all types. However, not all manufacturers cast all alloys. The use of inert gas and vacuum protection for melting and pouring has enabled the industry to cast the ultrahigh-temperature iron- and nickel-base precipitation-hardening alloys.

Sizes and Configurations

The size of investment castings is often thought of in terms of castings weighing less than 2.8 g to castings weighing about 1500 g; this size range includes a majority of the castings poured. However, the capability of the process permits the successful casting of parts over 50,000 g in over 500 mm in diameter with considerable accuracy and detail. Small castings have been produced with edges down to 0.38 mm, holes 3.2 mm in diameter by 152–203 mm long, and shorter holes to 0.076 mm. The type of alloy selected and the corresponding pouring practice may modify the maximum or minimum sizes and tolerances.

Applications

One of the major uses of investment-cast parts is in gas turbines. Investment-cast parts have proved very successful here because the shapes required (airfoils) are particularly difficult to machine and the high-strength alloy being used is difficult to finish, even for fairly simple operations. Many of the alloy compositions develop their outstanding properties in the cast form and may not be amenable to working in the wrought form.

No single industry, other than the gas-turbine industry, uses a large volume of investment castings. However, practically all industries are using some investment castings in their products or processes.

Advantages of the Process

There are several important advantages in the mass production of metal parts by the investment-casting process, not only by comparison with other casting processes but also with other production methods such as machining or forging.

Compared with other casting processes (such as sand or shell molding), investment casting provides the following:

1. An improved casting from the standpoint of cleanliness of the alloy and metallurgical soundness. This is especially true when an inert gas or vacuum is used to protect the alloy.
2. Considerably more versatility in producing intricate shapes and cast detail. This feature opens the possibility of combining two or more components of an assembly into a single casting.
3. Greater dimensional accuracy, which in many cases eliminates or minimizes the need for finishing. This certainly reduces the necessary stock allowance.
4. Better cast surfaces, which are beneficial from the standpoint of quality and appearance. This may further eliminate or minimize finishing operations.

The advantages of investment casting compared with other manufacturing processes are the following:

1. Many alloy compositions develop their outstanding properties in the cast form only. Also, many of the compositions cannot be produced other than in cast form.
2. There has always been controversy whether cast parts could compete with the consistent high quality and uniformity of forged parts. The investment-casting industry has proved this can be done, primarily, by consistently producing to the stringent quality requirements of the aircraft industry.
3. There have been many instances on both small and large parts where castings have been very beneficial in eliminating great amounts of machining, either starting with a wrought mill stock or from forged parts. Castings also have greater versatility and accommodating changes in section and shape.

Investment Compound

A mixture of a graded refractory filler, a binder, and a liquid vehicle, used to make molds for *investment casting*.

Investment Precoat

An extremely fine investment coating applied as a thin slurry directly to the surface of the pattern to reproduce maximum surface smoothness. The coating is surrounded by a coarser, cheaper, and more permeable investment to form the mold. See also *dip coat* and *investment casting*.

Investment Shell

Ceramic mold obtained by alternately dipping a pattern set up in *dip coat* slurry and stuccoing with coarse ceramic particles until the shell of desired thickness is obtained. See also *investment casting*.

Iodine

Iodine is a purplish-black, crystalline, poisonous elementary solid, with chemical symbol I, best known for its use as a strong antiseptic in medicine, but also used in many chemical compounds and

war gases. In tablet form, it is used for sterilizing drinking water and has lesser odor and taste than chlorine for this purpose. It is also used in cattle feeds. Although poisonous in quantity, iodine is essential to proper cell growth in the human body and is found in every cell in a normal body, with larger concentration in the thyroid gland.

A wide range of compounds are made for electronic and chemical uses. Iodine is also a chemical reagent, used for reducing vanadium pentoxide and zirconium oxide into high-purity metals.

Ion

An atom, or group of atoms, that by loss or gain of one or more electrons has acquired an electric charge. If the ion is formed from an atom of hydrogen or an atom of a metal, it is usually positively charged; if the ion is formed from an atom of a nonmetal or from a group of atoms, it is usually negatively charged. The number of electronic charges carried by an ion is termed its electrovalence. The charges are denoted by superscripts that give their sign and number, for example, a sodium ion, which carries one positive charge, is denoted by Na^+ and a sulfate ion, which carries two negative charges, by SO_4^{2-} . See also *atomic structure* and *chemical bonding*.

Ion Beam–Assisted Deposition

See *ion implantation*.

Ion Beam Mixing

See *ion implantation*.

Ion Beam Sputtering

See *ion implantation*.

Ion (ic) Bombardment/Plating/Scrubbing

Process in which a component in a vacuum or suitable gas at low pressure forms the cathode of an electrostatic circuit and is impacted by positive ions as a means of revealing structure, plating, or cleaning.

Ion Carburizing

A method of surface hardening in which carbon ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma carburizing or glow-discharge carburizing.

Ion Chromatography

An area of high-performance liquid chromatography that uses ion-exchange resins to separate various species of ions in solution and elute them to a suitable detector for analysis. See also *chromatography*, *gas chromatography*, and *liquid chromatography*.

Ion Etching

Surface removal by bombarding with accelerated ions in the vacuum (1–10 kV).

Ion Exchange

The reversible interchange of ions between a liquid and solid, with no substantial structural changes in the solid.

Ion Exchange (Ceramics)

An exchange of ions between two materials in intimate contact, usually accomplished by the application of heat.

Ion-Exchange Chromatography

Liquid chromatography with a stationary phase that possesses charged functional groups. This technique is applicable to the separation of ionic (charged) compounds. See also *ion chromatography*.

Ion-Exchange Resins

Cross-linked polymers that form salts with ions from aqueous solutions.

Ion Implantation

The process of modifying the physical or chemical properties of the near surface of a solid (target) by embedding appropriate atoms into it from a beam of ionized particles. The properties to be modified maybe electrical, optical, or mechanical, and they may relate to the semiconducting behavior of the material or its corrosion behavior. The solid may be crystalline, polycrystalline, or amorphous and need not be homogeneous. Related techniques are also used in conjunction with ion implantation to increase the ratio of material introduced into the substrate per unit area, to provide appropriate mixtures of materials, or to overcome other difficulties involved in surface modification by ion implantation alone. These techniques include the following:

1. *Ion beam sputtering*: An ion beam of argon or xenon directed at a target sputters material from the target to a substrate; the sputtered material arrives at the substrate with enough energy to promote good adhesion of the coating to substrate.
2. *Ion beam mixing*: Deposited layers (electroplating, sputtering) tens or hundreds of nanometers thick are mixed and bonded to the substrate by an argon or xenon ion beam.
3. *Plasma ion deposition*: Ion beams are used to create coatings having special phases, especially ion beam-formed carbon coatings in the diamond phase or ion beam-formed boron nitride coatings.
4. *Ion beam-assisted deposition*: Ion beams are combined with physical vapor deposition.

Ion Migration

The movement the free ions within a material or across the boundary between two materials under the influence of an applied electric field.

Ion Neutralization

The generic term for a class of charge-exchange processes in which an ion is neutralized by passage through a gas or by interaction with a material surface.

Ion Nitriding

A method of surface hardening in which nitrogen ions are diffused into a workpiece in a vacuum through the use of high-voltage electrical energy. Synonymous with plasma nitriding or glow-discharge nitriding.

Ion Plating

A generic term applied to atomistic film deposition processes in which the substrate surface and/or the depositing film is subjected to a flux of high-energy particles (usually gas ions) sufficient to cause changes in the interfacial region or film properties. Such changes may be in film adhesion to the substrate, film morphology, film density, film stress, or surface coverage by the depositing film material.

Ion Species

Type and charge of an ion. If an isotope is used, it should be specified.

Ionic Bond

(1) A type of chemical bonding in which one or more electrons are transferred completely from one atom to another, thus converting the neutral atoms into electrically charged ions. These ions are approximately spherical and attract each other because of their opposite charges. (2) A primary bond arising from the electrostatic attraction between two oppositely charged ions. Contrast with *covalent bond*. See *interatomic bonding*.

Ionic Charge

The positive or negative charge of an ion.

Ionic Conduction

Conduction arising from the movement of ions rather than electrons or holes.

Ionic Crystal

A crystal in which atomic bonds are *ionic bonds*. This type of atomic linkage, also known as (hetero) polar bonding, is characteristic of many compounds (sodium chloride, for instance).

Ionization

(1) The process in which neutral atoms become charged by gaining or losing an electron. (2) The act of splitting into, or producing, ions.

Ionization Chamber

An enclosure containing two or more electrodes surrounded by a gas capable of conducting an electric current when it is ionized by x-rays or other ionizing rays. It is commonly used for measuring the intensity of such radiation.

Ionomer Resins

A polymer that has ethylene as its major component, but that contains both covalent and ionic bonds. The polymer exhibits very

strong interchain ionic forces. The anions hang from the hydrocarbon chain, and the cations are metallic, for example, sodium, potassium, or magnesium. These resins have many of the same features as polyethylene, plus high transparency, tenacity, resilience, and increased resistance to oils, greases, and solvents. Fabrication is accomplished as it is with polyethylene.

Ion-Pair Chromatography

Liquid chromatography with a mobile phase containing an ion that combines with sample ions, creating neutral ion pairs. The ion pairs are typically separated using bonded-phase chromatography. See also *bonded-phase chromatography*.

Ion-Scattering Spectrometry

A technique to elucidate composition and structure of the outermost atomic layers of a solid material, in which principally monoenergetic, singly charged, low-energy (less than 10 keV) probe ions are scattered from the surface and are subsequently detected and recorded as a function of the energy.

IRG Transition Diagram

Developed by the International Research Group (IRG) on Wear of Engineering Materials of the Organization of Economic Cooperation and Development, it is a plot of normal force in newtons (ordinate) versus sliding velocity in meters per second (abscissa) wherein boundaries identify three distinct regions of varying lubricant effectiveness.

Iridescence

Loss of brilliance in metallized plastics and development of multi-color reflectance. Iridescence is caused by the cold flow of plastic or of coating and by excess heat during vacuum metallizing.

Iridium

Iridium (symbol Ir) is a grayish-white metal of extreme hardness. It is insoluble in all acids and in aqua regia. The melting point is 2447°C, and the specific gravity is 22.50. It occurs naturally with the metal osmium as an alloy, known as osmiridium, 30%–60% osmium, used chiefly for making fountain-pen points and instrument pivots.

Iridium is employed as a hardener for platinum, the jewelry alloys usually containing 10%. With 35% iridium, the tensile strength of platinum is increased to 965 MPa. Iridium wire is used in spark plugs because it resists attack of leaded aviation fuels. Iridium-tungsten alloys are used for springs operating at temperatures to 800°C. Iridium intermetallic compounds such as Cb_3Ir_2 , Ti_3Ir , and ZrIr_2 are superconductors.

Upon atmospheric exposure, the surface of the metal is covered with a relatively thick layer of iridium dioxide (IrO_2). Only when heated to redness is the metal attacked by oxygen (to give IrO_2) and by the halogens. The vapor pressure of IrO_2 is atm (10^5 Pa) at 1120°C, and consequently pieces of iridium metal lose mass at elevated temperatures in an oxygen atmosphere.

Metallic iridium is available in powder, sponge, wire, and sheet forms. Iridium is usually difficult to forge and fabricate, but it is ductile when hot and consequently is worked hot. It remains ductile when cooled as long as it is not annealed. Annealing causes loss of

ductility and brittleness. In the absence of oxygen, iridium is not attacked by many molten metals, including lithium, sodium, potassium, gold, lead, and tin.

Uses

Because of its scarcity and high cost, applications of iridium are severely limited. Although iridium metal and many of its complex compounds are good catalysts, no large-scale commercial application for these has been developed. In general, other platinum metals have superior catalytic properties. The high degree of thermal stability of elemental iridium and the stability it imparts to its alloys do give rise to those applications where it has found success. Particularly relevant are its high melting point (2443°C), its oxidation resistance, and the fact that it is the only metal with good mechanical properties that survives atmospheric exposure above 1600°C. Iridium is alloyed with platinum to increase tensile strength, hardness, and corrosion resistance. However, the workability of these alloys is decreased. These alloys find use as electrodes for anodic oxidation, for containing and manipulating corrosive chemicals, for electrical contacts that are exposed to corrosive chemicals, and as primary standards for weight and length. Platinum-iridium alloys are used for electrodes in spark plugs that are unusually resistant to fouling by antiknock lead additives. Iridium-rhodium thermocouples are used for high-temperature applications, where they have unique stability. Very pure iridium crucibles are used for growing single crystals of gadolinium gallium garnet for computer memory devices and of yttrium aluminum garnet for solid-state lasers.

Iridium-columbium intermetallic compounds have been identified as a potential material for high-temperature aircraft-turbine parts because of its high melting temperature and room-temperature ductility; it has a specific gravity of 15.2 and melts at 1900°C.

Iron

Iron (symbol Fe) is one of the most common of the commercial metals. It has been in use since the most remote times, but it does not occur native except in the form of meteorites—early tools of Egypt were apparently made from nickel irons from this source. The common iron ores are magnetic pyrites, magnetite, hematite, and carbonates of iron. To obtain the iron, the ores are fused to drive off the oxygen, sulfur, and impurities. The melting is done in a blast furnace directly in contact with the fuel and with limestone as a flux. The latter combines with the quartz and clay, forming a slag that is readily removed. The resulting product is crude pig iron, which requires subsequent remelting and refining to obtain commercially pure iron. Sintered iron and steel are also produced without blast-furnace reduction by compressing purified iron oxide in rollers, heating to 1204°C, and hot strip rolling. The final cold-rolled product is similar to conventional iron and steel.

Originally, all iron was made with charcoal, but because of the relative scarcity of wood and the greater expense, charcoal is now seldom used in the blast furnace.

Iron is a grayish metal, which until recently was never used pure. It melts at 1525°C and boils at 2450°C. Even very small additions of carbon reduce the melting point. It has a specific gravity of 7.85. Iron containing more than 0.15% chemically combined carbon is termed steel. When the carbon is increased to above about 0.40%, the metal will harden when cooled suddenly from a red heat.

Iron, when pure, is very ductile, but a small amount of sulfur, as little as 0.03%, will make it hot-short, or brittle at red heat. As little

as 0.25% of phosphors will make iron cold-short, or brittle when cold. Iron forms carbonates, chlorides, oxides, sulfides, and other compounds. It oxidizes easily and is also attacked by many acids.

Because pure iron is allotropic, it can exist in a solid in two different crystal forms. From subzero temperatures up to 910°C, it has a body-centered cubic structure and has been identified as alpha (α) iron. Between 910°C and 1400°C, the crystal structure is face-centered cubic. This form is known as gamma (γ) iron. At 1400°C and up to its melting point of 1540°C, the structure again becomes body-centered cubic. This last form, called delta (δ) iron, has no practical use. The transformation from one allotropic form to another is reversible. Thus, when iron is heated to above 910°C, the alpha body-centered cubic crystal changes into face-centered cubic crystals of gamma iron. When cooled below this temperature, the metal again reverts back to a body-centered cubic structure. These allotropic phase changes inherent in iron make possible the wide variety of properties obtainable in ferrous alloys by various heat-treating processes.

Types

Electrolytic iron is a chemically pure iron produced by the deposition of iron in a manner similar to electroplating. Bars of cast iron are used as anodes and dissolved in electrolyte of ferrous chloride. The current precipitates almost pure iron on the cathodes, which are hollow steel cylinders. The deposited iron tube is removed by hydraulic pressure or by splitting and then annealed and rolled into plates. The iron is 99.9% pure and is used for magnetic cores and where ductility and purity are needed.

Iron powder is made by reducing iron ore by the action of carbon monoxide at a temperature below the melting point of the iron and below the reduction point of the other metallic oxides in the ore. In the United States, it is made by the reduction of iron oxide mill scale, by electrolysis of steel borings and turnings in an electrolyte of ferric chloride, or by atomization. Iron powders are widely used for pressed and sintered structural parts, commonly referred to as powder metallurgy (P/M) parts. Pure iron powders are seldom used alone for such parts. Small additions of carbon in the form of graphite and/or copper are used to improve performance properties.

Iron-copper powders contain 2%–11% copper. Small amounts of graphite are sometimes added. Copper increases strength and hardness and improves corrosion resistance, but lowers ductility somewhat. Tensile strength ranges from 206 to 680 MPa, depending on density and heat treatment.

Iron-carbon powders contain up to 1% graphite. When pressed and sintered, internal carburization results and produces a carbon-steel structure, although some free carbon remains. In general, the density of structural or mechanical iron-carbon steel P/M parts is 80%–95% that of wrought steels, and the greater the density, the greater the strength and other mechanical properties. These carbon-steel P/M parts have a higher strength and hardness than those of iron, but they are usually more brittle. As-sintered strengths range from about 241 to 482 MPa depending on density. By heat treatment, strengths up to 861 MPa are achieved. P/M parts can be made to control porosity for filters or for filling with oil or other materials for surface lubricity.

Wrought iron refers usually, in a metallurgical context, to low-carbon iron containing elongated inclusions and made, in the final stages, by repeated folding and forging. See *wrought iron*.

Cast irons are iron alloys with carbon contents of about 2%–4%. Note that the cast-iron industry commonly omits the term “cast” in descriptions such as “malleable (cast) iron,” “gray (cast) iron,” and even (cast) “irons.” See *cast iron*. See also *blast furnace*.

Iron Alloys

These are solutions of metals, where one metal is iron. A great number of commercial alloys have iron as an intentional constituent. Iron is the major constituent of wrought and cast iron and wrought and cast steel. Alloyed with usually large amounts of silicon, manganese, chromium, vanadium, molybdenum, niobium, selenium, titanium, phosphorus, or other elements, singly or sometimes in combination, iron forms a large group of materials known as ferroalloys that are important as addition agents in steelmaking. Iron is also a major constituent of many special-purpose alloys developed to have exceptional characteristics with respect to magnetic properties, electrical resistance, heat resistance, corrosion resistance, and thermal expansion. See Table I.1.

Iron-Aluminum Alloys

Although pure iron has ideal magnetic properties in many ways, its low thermal resistivity makes it unsuitable for use in ac magnetic circuits. Addition of aluminum in fairly large amounts increases the electrical sensitivity of iron, making the resulting alloys useful in such circuits.

Three commercial iron-aluminum alloys with moderately high permeability at low field strengths and high electrical resistance nominally contain 12% aluminum, 16% aluminum, and 16% aluminum with 3.5% molybdenum, respectively. These three alloys are classified as magnetically soft materials, that is, they become magnetized in a magnetic field but are easily demagnetized when the field is removed.

The addition of more than 8% aluminum to iron results in alloys that are too brittle for many uses because of difficulties in fabrication. However, addition of aluminum to iron markedly increases its resistance to oxidation. One steel containing 6% aluminum possesses good oxidation resistance up to 1300°C.

Iron-Carbon Alloys

The principal iron-carbon alloys or wrought iron, cast iron, and steel.

Wrought iron of good quality is nearly pure iron; its carbon content seldom exceeds 0.035%. In addition, it contains 0.075%–0.15% silicon, 0.10 to less than 0.25% phosphorus, less than 0.02% sulfur, and 0.06%–0.10% manganese. Not all of these elements are alloyed with the iron; part of them maybe associated with the intermingled slag that is a characteristic of this product. Because of its low carbon content, the properties of wrought iron cannot be altered in any useful way by heat treatment.

Cast iron may contain 2%–4% carbon and varying amounts of silicon, manganese, phosphorus, and sulfur to obtain a wide range of physical mechanical properties. Alloying elements (silicon, nickel, chromium, molybdenum, copper, titanium, and so on) may be added in amounts varying from a few tenths to 30% or more. Many of the alloy cast irons have proprietary compositions.

Steel is a generic name for a large group of iron alloys that include the plain carbon and alloy steels. The plain carbon steels represent the most important group of engineering materials known. Although any iron-carbon alloy containing less than about 2% carbon can be considered a steel, the American Iron and Steel Institute (AISI) standard carbon steels embrace a range of carbon contents from 0.06% maximum to about 1%. In the early days of the American steel industry, hundreds of steels with different chemical compositions were produced to meet individual demands of purchasers. Many of these steels differed only slightly from each other in chemical composition.

TABLE I.1

Some Typical Composition Percent Ranges of Iron Alloys Classified by Important Uses^a

Type	Fe	C	Mn	Si	Cr	Ni	Co	W	Mo	Al	Cu	Ti
Heat-resistant alloy castings	Bal. ^b	0.30–0.50	—	1–2	8–30	0–7

^a This table does not include any AISI standard carbon steels, alloy steels, or stainless and heat-resistant steels or plain or alloy cast iron for ordinary engineering uses; it includes only alloys containing at least 50% iron, with a few exceptions.

^b Bal., balance percent or composition.

Studies were undertaken to provide a simplified list of fewer steels that would still serve the various needs of fabricators and users of steel products. The Society of Automotive Engineers (SAE) and the AISI both periodically publish lists of steels, called standard steels, classified by chemical composition. These lists are published in the SAE Handbook and the AISI Steel Products Manuals. The lists are altered periodically to accommodate new steels and to provide for changes in consumer requirements. There are minor differences between some of the steels listed by the AISI and SAE.

A numerical system is used to indicate grades of standard steels. Provision also is made to use certain letters of the alphabet to indicate the steelmaking process, certain special additions, and steels that are tentatively standard. The basic numerals for the AISI classification and corresponding types of steels in this system include the first digit of the series designation, which indicates the type to which a steel belongs; thus, 1 indicates a carbon steel, 2 indicates a nickel steel, and 3 indicates a nickel–chromium steel. In the case of simple alloy steels, the second usually indicates the percentage of the predominating alloying element. Usually, the last two (or three) digits indicate the average carbon content in points, or hundredths of a percent. Thus, 2340 indicates a nickel steel containing about 3% nickel and 0.40% carbon.

All carbon steels contain minor amounts of manganese, silicon, sulfur, phosphorus, and sometimes other elements. At all carbon

levels, the mechanical properties of carbon steel can be varied to a useful degree by heat treatments that alter its microstructure. Above about 0.25%, carbon steel can be hardened by heat treatment. However, most of the carbon steel produced is used without a final heat treatment.

Alloy steels are steels with enhanced properties attributable to the presence of one or more special elements or of larger proportions of manganese or silicon than are present ordinarily in carbon steel. The major classifications of alloy steels are high strength, low alloy, AISI alloy, alloy tool, heat resisting, electrical, and austenitic manganese. Some of these iron alloys are discussed briefly in the following.

Iron–Chromium Alloys

An important class of iron–chromium alloys is exemplified by the wrought stainless and heat-resisting steels of the type 400 series of the AISI standard steels, all of which contain at least 12% chromium, which is about the minimum chromium content that will confer stainlessness. However, considerably less than 12% chromium will improve the oxidation resistance of steel for up to 650°C, as is true of AISI types 501 and 502 steels that nominally contain about 5% chromium and 0.5% molybdenum. A comparable group of heat- and corrosion-resistant alloys, generally similar to the 400 series of

I the AISI steels, is covered by the Alloy Casting Institute specifications for cast steels.

Corrosion-resistant cast irons alloyed with chromium contain 12%–35% of that element and up to 5% nickel. Cast irons classified as heat resistant contain 15%–35% chromium and up to 5% nickel.

During World War I, a high-carbon steel used for making permanent magnets contained 1%–6% chromium (usually around 3.5%); it was developed to replace the magnet steels containing tungsten that had been formerly but could not then be made because of a shortage of tungsten.

Iron–Chromium–Nickel Alloys

The wrought stainless and heat-resisting steels represented by the type 200 and the type 300 series of the AISI standard steels are important class of iron–chromium–nickel alloys. A comparable series of heat- and corrosion-resistant alloys is covered by specifications of the Alloy Casting Institute. Heat- and corrosion-resistant cast irons containing 15%–35% chromium and up to 5% nickel.

Iron–Chromium–Aluminum Alloys

Electrical-resistance heating elements are made of several iron alloys of this type. Nominal compositions are 72% iron, 23% chromium, 5% aluminum, and 55% iron, 37.5% chromium, 7.5% aluminum. The iron–chromium–aluminum alloys (with or without 0.5%–2% cobalt) have higher electrical resistivity and lower density than nickel–chromium alloys used for the same purpose. When used as heating elements in furnaces, the iron–chromium–aluminum alloys can be operated at temperatures of 2350°C maximum. These alloys are somewhat brittle after elevated-temperature use and have a tendency to grow or increase in length while at temperature, so that heating elements made from them should have additional mechanical support. Addition of niobium reduces the tendency to grow.

Because of its high electrical resistance, the 72% iron, 23% chromium, 5% aluminum alloy (with 0.5% cobalt) can be used for semi-precision resistors in, for example, potentiometers and rheostats.

Iron–Cobalt Alloys

Magnetically soft iron alloys containing up to 65% cobalt have higher saturation values than pure iron. The cost of cobalt limits the use of these alloys to some extent. The alloys also are characterized by low electrical resistivity and high hysteresis loss. Alloys containing more than 30% cobalt are brittle unless modified by additional alloying and special processing. Two commercial alloys with high permeability at high field strengths (in the annealed condition) contain 49% cobalt with 2% vanadium and 35% cobalt with 1% chromium. The latter alloy can be cold-rolled to a strip that is sufficiently ductile to permit punching and shearing. In the annealed state, these alloys can be used in either ac or dc applications. The alloy of 49% cobalt with 2% vanadium has been used in pole tips, magnet yokes, telephone diaphragms, special transformers, and ultrasonic equipment. The alloy of 35% cobalt with 1% chromium has been used in high-flux-density motors and transformers as well as in some of the applications listed for the higher-cobalt alloy.

Although seldom used now, two high-carbon alloys called cobalt steel were used formerly for making permanent magnets. These were both high-carbon steels. One contained 17% cobalt, 2.5% chromium, 8.25% tungsten; the other contains 36% cobalt, 5.75% chromium, 3.75% tungsten. These are considered magnetically hard materials as compared to the magnetically soft materials.

Iron–Manganese Alloys

The important commercial alloy in this class is an austenitic manganese steel (sometimes called Hadfield manganese steel after its inventor) that nominally contains 1.2% and 12%–13% manganese. This steel is highly resistant to abrasion, impact, and shock.

Iron–Nickel Alloys

The iron–nickel alloys exhibit a wide range of properties related to their nickel contents.

Nickel content of a group of magnetically soft materials ranges from 40% to 60%; however, the higher saturation value is obtained at about 50%. Alloys with nickel content of 45%–60% are characterized by high permeability and low magnetic losses. They are used in such applications as audio transformers, magnetic amplifiers, magnetic shields, coils, relays, contact rectifiers, and choke coils. The properties of the alloys can be altered to meet specific requirements by special processing techniques involving annealing in hydrogen to minimize the effects of impurities, grain-orientation treatments, and so on.

Another group of iron–nickel alloys, those containing about 30% nickel, are used for compensating changes that occur in magnetic circuits due to temperature changes. The permeability of the alloys decreases predictably with increasing temperature.

Low-expansion alloys are so-called because they have low thermal coefficients of linear expansion. Consequently, they are valuable for use as standards of length, surveyors' rods and tapes, compensating pendulums, balance wheels in timepieces, glass-to-metal seals, thermostats, jet-engine parts, electronic devices, and similar applications.

The first alloy of this type contains 36% nickel with small amounts of carbon, silicon, and manganese (totaling less than 1%). Subsequently, a 39% nickel alloy with a coefficient of expansion equal to that of low-expansion glasses and a 46% nickel alloy with a coefficient equal to that of platinum were developed. Another important alloy is one containing 42% nickel that can be used to replace platinum as lead-in wire in light bulbs and vacuum tubes by first coating the alloy with copper. An alloy containing 36% nickel and 12% chromium has a constant modulus of elasticity and low expansivity over a broad range of temperatures. Substitution of 5% cobalt for 5% nickel in the 36% nickel alloy decreases its expansivity. Small amounts of other elements affect the coefficient linear expansion, as the variations in heat treatment, cold-working, and other processing procedures.

A 9% nickel steel is useful in cryogenic and similar applications because of good mechanical properties at low temperatures. Two steels (one containing 10%–11% nickel, 3%–5% chromium, about 3% molybdenum, and lesser amounts of titanium and aluminum and another with 17%–19% nickel, 8%–9% cobalt, 3%–3.5% molybdenum, and small amounts of titanium and aluminum) have exceptional strength in the heat-treated (aged) condition. These are known as maraging steels.

Cast irons containing 14%–30% nickel and 1.75%–5.5% chromium possess good resistance to heat and corrosion.

Iron–Silicon Alloys

There are two types of iron–silicon alloys that are commercially important: the magnetically soft materials designated silicon or electrical steel and the corrosion-resistant, high-silicon cast irons.

Most silicon steels used in magnetic circuits contain 0.5%–5% silicon. Alloys with these amounts of silicon have high permeability, high

electrical resistance, and low hysteresis loss compared with relatively pure iron. Most silicon steel is produced in flat-rolled (sheet) form and is used in transformer cores, stators, and rotors of motors that are built up in laminated-sheet form to reduce eddy current losses. Silicon-steel electrical sheets, as they are called commercially, are made in two general classifications: grain oriented and nonoriented.

The grain-oriented steels are rolled and heat-treated in special ways to cause the edges of most of the unit cubes of the metal lattice to align themselves in the preferred direction of optimum magnetic properties. Magnetic cores are designed with the main flux path in the preferred direction, thereby taking advantage of the directional properties. The grain-oriented steels contain about 3.25% silicon, and they are used in the highest-efficiency distribution and power transformers and in large turbine generators.

The nonoriented steels may be subdivided into low-, intermediate-, and high-silicon classes. Low-silicon steels contain about 0.5%–1.5% silicon and are used principally in rotors and stators of motors and generators; steels containing about 1% silicon are also used for reactors, relays, and small intermittent-duty transformers. Intermediate-silicon steels contain about 2.5%–3.5% silicon and are used in motors and generators of average to high efficiency and small- to medium-size intermittent-duty transformers, reactors, and motors. High-silicon steels contain about 3.75%–5% silicon and are used in highest-efficiency motors, generators, and transformers.

High-silicon cast irons containing 14%–17% silicon and sometimes up to 3.5% molybdenum possess corrosion resistance that makes them useful for acid-handling equipment and for laboratory drainpipes.

Iron–Tungsten Alloys

Although tungsten is used in several types of relatively complex alloys (including high-speed steels), the only commercial alloy made up principally of iron and tungsten was a tungsten steel containing 0.5% chromium in addition to 6% tungsten that was used up to the time of World War I for making permanent magnets.

Hard-Facing Alloys

Hard-facing consists of welding a layer of metal of special composition on a metal surface to impart some special property not possessed by the original surface. The deposited metal may be more resistant to abrasion, corrosion, heat, or erosion than the metal to which it is applied. A considerable number of hard-facing alloys are available commercially. Many of these would not be considered iron alloys by the 50% iron content criterion adopted for the iron alloys. Among the iron alloys are low-alloy facing materials containing chromium as a chief alloying element, with smaller amounts of manganese, silicon, molybdenum, vanadium, tungsten, and in some cases nickel to make a total alloy content of up to 12%, with the balance iron. High-alloy ferrous materials containing a total of 12%–25% alloying elements form another group of hard-facing alloys; a third group contains 26%–50% alloying elements. Chromium, molybdenum, and manganese are the principal alloying elements of the 12%–25% group; smaller amounts of molybdenum, vanadium, nickel, and in some cases titanium are present in various proportions. In the 26%–50% alloys, chromium (and in some cases tungsten) is the principal alloying element, with manganese, silicon, nickel, molybdenum, vanadium, niobium, and boron as the elements from which a selection is made to bring the total alloy content within the 26%–50% range.

Permanent-Magnet Alloys

These are magnetically hard ferrous alloys, many of which are too complex to fit the simple compositional classification used earlier for other iron alloys. As already mentioned in discussing iron–cobalt and iron–tungsten alloys, the high-carbon steels (with or without alloying elements) are now little used for permanent magnets. These have been supplanted by a group of sometimes complex alloys with much higher retentivities. The ones considered here are all proprietary compositions. Two of the alloys contain 12% cobalt–17% molybdenum and 12% cobalt–20% molybdenum.

Members of a group of six related alloys contain iron, nickel, aluminum, and with one exception cobalt; in addition, three of the cobalt-containing alloys contain copper and one has copper and titanium. Unlike magnet steels, these alloys resist demagnetization by shock, vibration, or temperature variations. They are used in magnets for speakers, watt-hour meters, magnetrons, torque motors, panel and switchboard instruments, and so on, where constancy and degree of magnet strength are important.

Iron Carbide

A hard, brittle intermetallic compound of iron and carbon, having the approximate composition Fe_3C . Is also called *cementite*, which dominates *white cast iron*, a type of cast iron formed by rapid solidification of molten iron. Iron carbide has a density that is slightly less than that of pure iron. It is extremely hard, thus exceptionally wear resistant, retains high hardness up to red heat, has high compressive strength, and exhibits a white crystalline fracture. With suitable compositions, it can be induced to form in select regions of otherwise softer irons by the use of chills in these regions of a casting mold to affect more rapid solidification.

Iron Loss

The loss of power in an electrical circuit arising from eddy currents in the magnetic iron core of transformer.

Iron Powder Electrode

A welding electrode with a covering containing up to about 50% iron powder, some of which becomes part of the deposit.

Iron Pyrite

A mineral sometimes mined for the zinc, gold, or copper associated with it, but chiefly used for producing sulfur, sulfuric acid, and copperas. It is an *iron disulfide*, FeS_2 , containing 53.4% sulfur. It often occurs in crystals, also massive or granular. It is brittle, with a Mohs hardness of 6–6.5 and specific gravity 4.95–5.1. The color is brassy yellow and it is called *fool's gold* because of the common error made in detection. In the Italian method of roasting pyrites, oxygen combines with sulfur to form sulfur dioxide and with iron. *Pyrite* is found in rocks of all ages associated with different minerals. The pyrites mined in Missouri, known as *marcasite*, also used for gemstones, have the formula FeS , and the gem specimens have a yellow color with a greenish tinge. *Sulfur pyrites*, found in great quantity in Shasta County, California, are roasted to produce sulfuric acid, and the residue is used for making cement and ferric sulfate. In Japan, pyrite is chlorinated, producing sulfur, copper, gold, silver, and zinc, and the residue of sintered pellets of Fe_2O_3 is used in blast furnaces.

Iron Rot

Deterioration of wood in contact with iron-base alloys.

Iron Shot

An abrasive material made by running molten iron into water. It is employed in tumbling barrels and in the cutting and grinding of stones. The round sizes between No. 30 and No. 20 are used for the shot peening of mechanical parts to increase fatigue resistance. *Peening shot* is marketed by SAE numbers from 6 to 157, the size numbers being the diameter in thousandths of an inch. *Steel grit* is made by forcing molten iron through a steam jet so that the metal forms into small and irregular pieces, and large globules are crushed into steel grit in sizes from No. 8 to No. 80. It is preferred to sand for sandblasting some materials. *Steelblast* is this material for tumbling and sandblasting. All the materials for metal cleaning are termed *blasting shot*.

Iron Soldering

A soldering process in which the heat required is obtained from a soldering iron.

Ironing

An operation used to increase the length of a tube or cup through reduction of wall thickness and outside diameter, the inner diameter remaining unchanged.

Ironstone

A mineral, usually iron carbonate, containing a large proportion of iron.

Irradiance

The radiant flux density incident on a surface; the ratio of flux to area of irradiated surface.

Irradiation

The exposure of a material or object to x-rays, gamma-rays, ultraviolet rays, or other ionizing radiation.

Irradiation (Plastics)

The bombardment of plastics with a variety of subatomic particles, usually alpha-, beta-, or gamma-rays. Used to initiate the polymerization and copolymerization of plastics and in some cases to bring about changes in the physical properties of a plastic.

Irregular Powder

Particles lacking symmetry.

Irreversible (Plastics)

Not capable of redissolving or remelting. Chemical reactions that proceed in a single direction and are not capable of reversal (as applied to thermosetting resins).

Isinglass

A gelatin made from the dried swimming bladders, or *fish sounds*, of sturgeon and other fishes. *Russian isinglass* from the sturgeon is the most valued grade and is one of the best of the water-soluble adhesives. It is used in glues and cements and in printing inks. It is also used for clarifying wines and other liquids. It is prepared by softening the bladder in water and cutting it into long strips. These dry to a dull-gray, horny, or stringy material. It is used as an anti-septic astringent. The name *isinglass* was also used for mica when employed as a transparent material for stove doors.

ISO

International Standards Organization.

ISO Metric Fasteners

An ISO-approved system of sizes, tolerances, and materials for threaded fasteners. For steel fasteners, the material strength is identified by two numbers, the second being a decimal, for example, "12.9." The first number is 1/10 of the ultimate tensile strength (UTS) of the material in kgf/mm²; the second number is the yield to ultimate ratio as a decimal. Thus, in the example quoted, 12.9, the material has a UTS of 120 kgf/mm² and the yield strength is the UTS times 0.9, that is, 108 kgf/mm².

Isobar

(1) In atomic physics, one of two or more atoms that have a common mass number *A*, but differ in atomic number *Z*. Thus, although isobars possess approximately equal masses, they have different chemical properties; they are atoms of different elements. See also *nuclear structure*. (2) A line joining points of constant pressure.

Isocorrosion Diagram

A graph or chart that shows constant corrosion behavior with changing solution (environment) composition and temperature.

Isocratic Elution

In liquid chromatography, the use of a mobile phase with composition that is unchanged throughout the course of the separation process.

Isocyanate Plastics

Plastics based on resins made by the condensation of organic isocyanates and other compounds. Generally reacted with polyols on a polyester or polyether backbone molecule, with the reactants being joined by the formation of the urethane linkage. See also *polyurethane* and *urethane plastics*.

Isomer

A compound, radical, ion, or nuclide that contains the same number of atoms of the same elements but differs in structural arrangement and properties. See also *stereoisomer*.

Isometric

A crystal form in which the unit dimension on all three axes is the same.

Isomorphous

Having the same crystal structure. This usually refers to intermediate phases that form a continuous series of solid solutions.

Isomorphous System

A complete series of mixtures in all proportions of two or more components in which unlimited mutual solubility exists in the liquid and solid states.

Isopolyester Composites

An isopolyester composite is used to retrofit concrete causeway support columns. The Snap-Tite composite jacket will use isopolyester made with purified isophthalic acid. Isopolyesters have a proven record of delivering corrosion resistance and mechanical strength at less cost. The resin encapsulates the reinforcing network, which for most applications is conventional e-glass woven roving and bidirectional fabric. As a result, the compressive strength of the columns will reportedly more than double, 283 MPa or more, and the ductility will improve from 3% to 10%.

Isostatic

At equal pressure. In some, perhaps casual, usages, the term is used merely to indicate that pressure does not vary with time, but in a stricter sense, in terms such as hot isostatic pressing, it indicates that the pressure acts equally in all directions.

Isostatic Mold

A sealed container of glass or sheet of carbon steel, stainless steel, or a nickel-based alloy. See also *isostatic pressing*.

Isostatic Pressing

The isostatic pressing process was pioneered in the mid-1950s and has steadily grown from a research curiosity to a viable production tool. Many industries apply this technique for consolidation of powders or defect healing of castings. The process is used for a range of materials, including ceramics, metals, composites, plastics, and carbon.

Isostatic pressing applies a uniform, equal force over the entire product, regardless of shape or size. It thus offers unique benefits for ceramic and refractory applications. The ability to form product shapes to precise tolerances (reducing costly machining) has been a major driving force for its commercial development.

There are three basic types of isostatic pressing. Cold isostatic pressing (CIP) is applied to consolidate ceramic or refractory powders loaded into elastomeric bags. Warm isostatic pressing differs from CIP only in that shapes are pressed at warm temperature to about 100°C. Hot isostatic pressing involves both temperature and pressure applied simultaneously to obtain fully dense parts (to 100% theoretical density) and is used mainly for engineered ceramics requiring optimum properties for high-performance applications.

Cold Isostatic Pressing (CIP)

CIP is mainly a powder-compacting process for obtaining 60%–80% theoretically dense parts ready for sintering. Because of the good green strength obtained with this forming method, premachining before sintering is feasible without causing breakage.

When comparing uniaxial pressing to isostatic pressing, one can say that uniaxial pressing is more suitable for small shapes at high production rates. Die wall friction may result in nonuniform densities, especially for large aspect ratios (greater than 3:1).

CIP is slower than uniaxial pressing but can be used for small or large, simple or complex shapes. The uniform green density offers more even shrinkage during sintering, which is very important for good shape control and uniform properties. In addition, CIP does not require a wax binder as does uniaxial pressing, thus eliminating the waxing operations.

Low-cost elastomer tooling is used for isostatic pressing, but close tolerances can only be obtained for surfaces that are pressed against a highly accurate steel mandrel. Surfaces in contact with the elastomer tooling may require post machining when tight tolerances and good surface finishes are specified.

Wet-Bag CIP

Two types of CIP methods have evolved over the years; wet-bag and dry-bag. The so-called wet-bag method is used for producing mixed shapes. It is estimated that there are more than 3000 wet-bag presses in use worldwide today, ranging in size from 50 to 2000 mm in diameter.

A typical cycle time for a production press ranges from 5 to 30 min, depending mainly on size, powder volumetric compaction ratio, and pump selected. This speed is rather slow but can be improved by higher-volume pumps, better vessel use, and improved loading mechanisms. A 5 min cycle calculates to 24,000 annual cycles based on a 1-shift, 8 h operation, or 240,000 cycles in 10 years. That should be the minimum design value of a vessel. Therefore, it is very important to select the proper vessel design to meet the end user's specified fatigue requirements as proven by the supplier's theoretical analysis and past performance.

Dry-Bag CIP

The dry-bag process is more applicable to producing same-shaped parts. Automated dry-bag isostatic pressing equipment was developed in the 1930s for compacting spark plug insulators, which are exclusively produced that way today for worldwide distribution.

The dry-bag method involves the same flex-bag technology for powder containment as the wet bag except that a stationary polyurethane "master bag," called the membrane, is inserted inside the pressure vessel. The pressure force (water) is transmitted through the membrane to the mold and then to the powder, thus keeping the mold dry. Generally one part is pressed at a time, and loading occurs from the bottom.

A minimum of three cassettes (each cassette typically consisting of the mandrel, mold, and powder) are in motion simultaneously; one is pressed, one is filled with powder, and one is debagged. The cycle time is 1 min or less, which calculates to 120,000 cycles/year on a 1-shift, 8 h basis. This rate of cycling places a much higher demand on the pressure vessel fatigue, and proper design is critical to withstand the higher pressures. The dry-bag method is preferred over the wet-bag for automated production of same-size or same-shaped parts and lots of about 50 parts per hour or above.

Warm Isostatic Pressing (WIP)

WIP follows the same path as CIP except the parts are compacted both at pressure and low temperature to 100°C. The pressing fluid water may be substituted with oil. To date, there are a few applications for manufacturers in the electronics industry as a cost-effective means of compacting different shaped parts.

Traditionally, a heated platen press has been applied in these applications. The problem associated with this method is the lack of uniform pressure all around the parts, resulting in dimensional variations from one side to the other. WIP, on the other hand, is a well-suited alternative for applying equal and uniform pressure on all surfaces.

Hot Isostatic Pressing (HIP)

HIP is a densification method for powders, compacts, or castings. It applies a gas pressure of 100–200 MPa and temperatures to 2200°C. An inert gas, most commonly argon, is used as the pressing fluid. The goal was to improve the performance of critical parts by eliminating defects and porosity resulting in fully dense compacts. Improvements in mechanical and physical properties, fatigue, surface finish, reliability, and/or rejection rate are possible using HIP.

Two HIP methods are used today for compacting parts: direct HIP, which applies to encapsulated powders, and post-HIP, which applies to presintered compacts without interconnected porosity. (The HIP and CIP processes can also be combined, sometimes called CHIP. In CHIP, loose powder is cold-compacted, then sintered, and then post-HIPed to achieve fully dense parts.)

Direct HIP involves a ceramic powder enclosed in a container usually made from an impermeable barrier, such as glass, ceramic, or refractory metal. Glass is the most common barrier today for direct compacting of ceramic powders and serves in two ways: (1) it acts as a barrier for consolidation and (2) it isolates and protects the powder from the processing gas.

Several precompacting methods are available for direct HIP, including injection molding, slip casting, CIP, or dry pressing. After preforming, the parts are glass encapsulated prior to HIP. A major goal is to form parts to near-net configurations to minimize final machining, which usually requires expensive diamond tooling.

Post-HIP is an alternative method and is a widely practiced way to HIP products such as oxide ceramics, tool bits, and ferrites. This method is only valid for materials that are able to sinter without pressure to close surface-connected porosity, equivalent to about 92%–95% of theoretical density. The powder is shaped-formed by either casting or CIP, is then pressureless sintered, and finally post-HIP is employed for full densification. Post-HIP is also chosen when material decomposition is to be avoided; the post-HIP process allows the pressure fluid to contact the partially dense parts for reactive processing. For example, a mixture of 95% argon and 5% oxygen is preferred for oxide ceramics, whereas nitrogen gas is preferred for nitride ceramics.

The HIP process is rather slow, and a cycle may take 10–15 h, depending on part size, material, and furnace design. One of the reasons for the long cycle is that most installations use conventional furnaces that cool not only slowly but also not uniformly. Advanced furnaces are available with uniform rapid cooling provisions that have been used for metals since early 1990. Shorter cycle times improve throughput, thus reducing processing costs.

The rate of cooling is programmable from 1°C/min to 50°C/min. A variable-speed fan is used to select the appropriate rate to avoid cracking when processing thermally sensitive ceramic parts. This feature can reduce HIP cycles to less than 8 h but adds only 10%–15% to the equipment price.

One of the largest HIP units for processing ceramics is 0.64 m in diameter and is rated at 1850°C.

Versatile Process

Isostatic processing has found wide use for many different materials used in a variety of applications. CIP is mainly a powder consolidation process using inexpensive molds as barriers for compacting simple to complex shapes to 60%–80% densities. The selection of a “wet-bag” versus “dry-bag” method depends on the type, mix, and production lots of parts produced.

Warm isostatic pressing has found a niche in certain industries where combined pressure and low temperatures to 100°C are specified.

The HIP process is gaining momentum in the engineered ceramics field for obtaining near-net-shape and fully dense ceramics for high-performance applications. Either direct HIP or post-HIP may be selected, depending on the material or process specified.

Isotactic Stereoisomerism

A type of polymeric molecular structure containing a sequence of regularly spaced asymmetric groups arranged in like configuration in a polymer chain. Isotactic (and syndiotactic) polymers are crystallizable.

Isotherm

A line joining points of equal temperature.

Isothermal

Occurring at a single temperature. Isothermal reactions occur over a period of time and involve an input or output of heat.

Isothermal Annealing

Austenitizing a ferrous alloy and then cooling to and holding at a temperature at which austenite transforms to a relatively soft ferrite–carbide aggregate. See also *austenitizing of steel*.

Isothermal Forging

To meet the increasing forging demands of the aerospace turbine engine industry, a highly integrated, state-of-the-art isothermal forging cell has been developed. The cell has the capacity to meet 100% of the current and projected industry needs for superalloys, isothermally forged turbine engine components.

Equipment within the isothermal forging cell includes an 8000-ton clearing press, a 1204°C heat treatment furnace, and customized, computer-controlled ultrasonic inspection equipment. The cell can completely produce and process (forge, machine, heat treat, and inspect) isothermally forged engine components within one facility.

Process

A hot forging process in which a constant and uniform temperature is maintained in the workpiece during forging by heating the die to the same temperature as the workpiece. The process permits the use of extremely slow strain rates, thus taking advantage of the strain rate sensitivity of flow stress for certain alloys (e.g., titanium- and nickel-base alloys). The process is capable of producing net-shape forgings that are ready to use without machining or near-net-shape forgings that require minimal secondary machining.

Advantages of ISO

The aircraft industry is increasing its use of nickel-based powder alloys. These alloys allow for the manufacture of higher-performing aircraft components that can withstand higher temperatures and greater stress than those manufactured from more traditional wrought alloys. Powder alloys must be extruded and consolidated into a billet, which is then forged and machined to its final net shape.

In addition to these qualitative advantages of utilizing powder alloys, isothermal forging offers a number of performance and production capacity advantages. Isothermal forging is a process in which the billet and the forging dies are heated to the same temperatures. This allows for a nearer net-shape forging, thus reducing the amount of material necessary to produce the part as always reducing machining requirements. A reduction in machining requirements reduces materials waste and improves throughput.

The use of an ISO cell has resulted in a significant increase in productivity where the average cycle time has been reduced by 30%–40%, with machining times reduced by as much as 50%. Forging press setup time has been reduced by up to 50% and downtime is less than 5%. All total, these enhancements to productivity have resulted in significant unit cost reductions.

Isothermal Transformation

A change in phase that takes place at a constant temperature. The time required for transformation to be completed and, in some instances, the time delay before transformation begins depends on the amount of supercooling below (or superheating above) the equilibrium temperature for the same transformation.

Isothermal Transformation Diagram

A diagram indicating the phase changes that occur in a steel quenched from the austenitic state to various temperatures. See *steel*. These diagrams are also termed time, temperature, transformation diagrams for obvious reasons or “S” curves because of the shape of the transformation boundaries in some of the diagrams. The concept of the diagram is that it indicates the changes undergone by a steel after it has been quenched to the temperature in question and held at that level until all transformation is complete or equilibrium is reached. Transformation to ferrite/carbide structures, including bainites, is diffusion controlled and hence time dependent, so the diagram indicates the progress of transformation to these phases as time elapses. See also *austenite*. Transformation to martensite is, effectively, an instantaneous shear process, not time controlled but temperature dependent. The diagram therefore indicates the percentage transformation to martensite at any temperature. As noted, the diagram assumes instantaneous quenching from the austenitic region to the temperature in question. Such idealized conditions are not met in commercial practice where bulk components cannot be instantaneously quenched and where cooling is continuous rather than isothermal. Consequently, the diagrams have to be used with some caution. However, if it is possible to superimpose on the diagram, curves correspond to the cooling of, for example, the exterior and center of a particular size bar. Such diagrams, termed continuous cooling transformation diagrams will give a good indication of the structure and properties likely to be achieved. The basic diagram is also of value in devising treatments such as martempering, austempering, and ausforming in which the steel is rapidly cooled to an intermediate temperature, held for a period insufficient for transformation to commence, and then cooled to ambient.

Isotone

One of two or more atoms that display a constant difference $A-Z$ between their mass number A and their atomic number Z . Thus, despite differences in the total number of nuclear constituents, the number of neutrons in the nuclei of isotones is the same. See also *nuclear structure*.

Isotope

One of two or more nuclidic species of an element having an identical number of protons (Z) in the nucleus, but a different number of neutrons (N). Isotopes differ in mass, but chemically are the same element. See also *nuclear structure*.

Isotropic

Having uniform properties in all directions. The measured properties of an isotropic material are independent of the axis of testing.

Isotropy

The condition of having the same values of properties in all directions.

Item

(1) An object or quantity of material on which a set of observations can be made. (2) Been observed value or test result obtained from an object or quantity of material.

Ivory

The material that composes the tusks and teeth of the elephant. It is employed mostly for ornamental parts, art objects, and piano keys, although the latter are now usually a plastic which does not yellow. The color is the characteristic ivory white, which yellows with age. The specific gravity is 1.87. The best grades are from the heavy tusks weighing more than 55 lb (25 kg), sometimes 6 ft (1.8 m) long. The ivory from animals long dead is a gray color and inferior. The softer ivory from elephants living in the highlands is more valuable than the hard and more brittle ivory of the low marshes. The west coast of Africa, India, and southern Asia are the chief sources of ivory. The tusks of the hippopotamus, walrus, and other animals, as well as the fossil mammoth of Siberia, also furnish ivory, although of inferior grades. *Odontolite* is ivory from fossil mammoths of Russia. Ivory can be sawed readily and is made into thin veneers for ornamental uses. It takes a fine polish. Artificial ivory is usually celluloid or synthetic resins.

Izod Test

A type of impact test in which a V-notched specimen, mounted vertically, is subjected to a sudden blow delivered by the weight at the end of a pendulum arm. The energy required to break off the free end is a measure of the impact strength or toughness of the material. Contrast with *Charpy test*.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

Jacquet Polishing

Electrolytic polishing particularly for metallographic examination. See *electrochemistry*.

Jam Nut

See *lock nut*.

Jaw Crusher

A machine for the primary disintegration of metal pieces, ores, or agglomerates into coarse powder. See also *crushing*.

Jeffries' Method

A method for determining grain size based on counting grains in a prescribed area.

Jet Molding

A processing technique for plastics characterized by the fact that most of the heat is applied to the material as it passes through the nozzle or jet, rather than in a heating cylinder, as is done in conventional processes.

Jet Pulverizer

A machine that comminutes metal pieces, ores, or agglomerates by means of pressurized air or steam injected into a chamber.

Jet Test

Various laboratory tests in which a jet of liquid impinges on the surface of the material in question to determine its corrosion characteristics under flowing conditions. See *B.N.F. jet impingement test*.

Jetting (Plastics)

The turbulent flow of resin from an undersized gate or thin section into a thicker mold cavity, as opposed to the laminar flow of material progressing radially from a gate to the extremities of the cavity.

Jetting (Welding)

The flow process and expulsion of the metal surface that takes place during *explosion welding*.

Jewel Bearing

A bearing made of diamond, sapphire, or a hard substitute metal.

Jewelers Rouge

Red iron oxide, hematite, Fe_2O_3 , in fine powder form used as an abrasive and polish. It is now little used for metallography as it smears rather than cutting cleanly like diamond paste.

Jewelry Alloys

An indefinite term that refers to the casting alloys used for novelties to be plated and to the copper and other nonferrous sheet and strip alloys for stamped and turned articles. The base-metal jewelry industry, as distinct from the precious-metal industry, produces costume jewelry, trinkets, souvenirs, premium and trade goods, clothing accessories known as notions, and low-cost religious goods such as medals and statuettes. The soft white alloys of this type are not now as important as they were before the advent of plastics, and articles now produced in metals are likely to be made from standard brasses, nickel brasses, and copper-nickel alloys, but laminated and composite sheet metals are much used to eliminate plating. With the base metals clad or plated with gold, they are called *gold-filled metal* if the gold alloy is 10-karat or above and the amount used is at least 5% of the total weight. When the coating is less than 5%, it is called *rolled-gold plate*. Formally, a great variety of trade names were used for jewelry alloys. *Platinoid* was a nickel-silver-tungsten alloy with a small amount of tungsten added to the melt in the form of phosphor tungsten. *Proplatinum*, another substitute for platinum, was a nickel-silver-bismuth alloy. *Nuremberg gold*, with a nontarnishing golden color, contained 90% copper, 7.5% aluminum, and 2.5% gold.

Jig

A mechanism for holding a part and guiding the tool during machining or assembly operation.

Jig Boring

Boring with a single-point tool where the work is positioned upon a table that can be located so as to bring any desired part of the work under the tool. Thus, holes can be accurately spaced. This type of boring can be done on milling machines or jig borers.

Jig Grinding

Analogous to *jig boring*, where the holes are ground rather than machined.

J-Integral

A mathematical expression; a line or surface integral that encloses the crack front from one crack surface to the other, used to characterize the *fracture toughness* of a material having appreciable plasticity before fracture. The *J-integral* eliminates the need to describe the

behavior of the material near the crack tip by considering the local stress–strain field around the crack front; J_{Ic} is the critical value of the J -integral required to initiate growth of a preexisting crack. It is analogous to ‘K’ in a brittle material. See *fracture toughness*.

Jog

A step in a dislocation produced when the dislocation traversed another.

Joggle

An offset in a flat plain consisting of two parallel bends at the same angle but in opposite directions.

Johnson Noise

See *thermal noise*.

Joint

The location where two or more members are to be or have been fastened together mechanically or by welding, brazing, soldering, or adhesive bonding.

Joint Buildup Sequence

See *buildup sequence*.

Joint Clearance

The distance between the faying surfaces of a joint. In brazing, this distance is referred to as that which is present before brazing, at the brazing temperature, or after brazing is completed.

Joint-Conditioning Time

In adhesive bonding, the time interval between the removal of the joint from the conditions of heat or pressure, or both, used to accomplish bonding and the attainment of approximately maximum bond strength. See also *curing time*, *drying time*, and *setting time*.

Joint Design

The joint geometry together with the required dimensions of the welded joint.

Joint Efficiency

The strength of a welded joint expressed as a percentage of the strength of the unwelded base metal.

Joint Geometry

The shape and dimensions of a joint in cross section prior to welding.

Joint Penetration

The minimum depth to which a groove or flange weld extends from its face into the joint, exclusive of reinforcement. Joint penetration may include *root penetration*.

Joint Severity (of Weld)

See *weldability*.

Jolt Ramming

Packing sand in a mold by raising and dropping the sand, pattern, and flask on a table. Jolt-type, jolt-squeezer, jarring, and jolt-ramming machines are using this principle. Also called a jar ramming.

Jolt-Squeezer Machine

A combination machine that employs a jolt action followed by a squeezing action to compact the sand around the pattern.

Jominy (End Quench) Test

(1) A test for assessing the hardenability of steel in which a standard bar specimen is heated to the austenitic range and then one end is quenched by a jet of water. This results in a progressive variation in cooling rate along the bar. Following cooling the bar is tested for hardness along its length to determine the extent of hardening, and it may also be metallographically examined to establish the limit of the martensitic and bainitic zones. (2) A laboratory test for determining the hardenability of steel that involves heating the test specimen to the proper *austenitizing* temperature and then transferring it to a quenching fixture so designed that the specimen is held vertically 12.7 mm (0.5 in.) above an opening through which a column of water can be directed against the bottom face of the specimen. While the bottom end is being quenched by the column of water, the opposite end is cooling slowly in air, and intermediate positions along the specimen are cooling at intermediate rates. After the specimen has been quenched, parallel flats 180° apart are ground 0.38 mm (0.015 in.) deep on the cylindrical surface. Rockwell C hardness is measured at intervals of 1/16 in. (1.6 mm) for alloy steels and 1/32 in. (0.8 mm) for carbon steels, starting from the water-quenched end. A typical plot of these hardness values and their positions on the test bar indicates the relation between hardness and cooling rate, which in effect is the hardenability of the steel. Also referred to as *end-quench hardenability test*.

Joule

The SI unit of energy, symbol J, quantity of heat or work done. One joule is the work done when the point of application of a force of 1 N is displaced by 1 m. Also, in other terms, 1 J = 0.728 ft lb = 1 W s = 0.239 cal.

Joule Effect

(1) The heat resulting from the passage of an electric current. It is expressed as $J = I^2RT$, where I is the current in amps, R is the resistance of the conductor in ohms, and T is the time in seconds. (2) See *magnetostriction*.

Joule–Thompson Effect

A change in temperature in a gas undergoing Joule–Thompson expansion. See also *Joule–Thompson expansion*.

Joule–Thompson Expansion

The adiabatic, irreversible expansion of a gas flowing through a porous plug or partially open file. See also *Joule–Thompson effect*.

Journal

The part of a shaft or axle that rotates or oscillates relative to a radial bearing. A journal was part of a larger unit, for example, a crankshaft or lineshaft, and it is preferred that the term shaft be kept for the whole unit.

Journal Bearing

A sliding-type bearing in which a journal rotates or oscillates relative to its housing. A full journal bearing extends 360°, but partial bearings may extend, for example, over 180° or 120°. See also the term *solid lubrication*.

Jute

A fiber employed for making burlap, sacks, cordage, ropes, and upholstery fabrics. It is obtained from several plants in India where it is most widely cultivated, growing in a hot, steamy climate. Also fiber from Brazil is called *juta indiana*, or *Indian jute*. Most of the commercial jute comes from Bengal. The plant grows in tall, slender stalks like hemp, and the fiber is obtained by retting and cleaning. The fibers are long, soft, and lustrous, but are not as strong as hemp. It also loses its strength when damp, but is widely used because of its low cost and because of the ease with which it can be spun. Its chemical composition is intermediate between those of hemp and kapok. It contains 60% alpha cellulose, 15% pentosan, 13% lignin, and 4.5% *uronic anhydride*, which is also a constituent of kapok. The butts, or short ends of the stalks, and the rough fibers are used for paper stock. *Jute paper*, used for cement bags, is a strong paper made of these fibers usually mixed with old rope and old burlap in the pulping. It is tan in color. *Jute fiber* is also used for machine packings.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

K

K

Temperature in Kelvin.

 K , K_{IC} , etc.

K is the stress-intensity factor defining the relationship, at the crack tip, between stress and crack size. The numerical subscripts identify the mode of cracking, for example, “I” indicates the common case of the crack being pulled open. The subscript “C” indicates a critical level of K at which a crack will extend. See *fracture toughness*.

Kaldo Process

One of the first oxygen steelmaking processes. In the process, a stream of oxygen impinges on the surface of molten steel in a rotating converter vessel. The vessel has a basic lining with a lime flux, and the process removes both carbon and phosphorus from high-phosphorus pig iron. The use of oxygen is of choice and nitrogen pick up associated with air lancing.

Kaolin (China Clay)

The two terms are used interchangeably to describe a type of clay that fires to a white color. The name kaolin comes from the two Chinese words kao–ling, meaning high ridge, and was originally a local term used to describe the region from which the clay was obtained.

Kaolin ($Al_2O_3 \cdot 2SiO_2 \cdot 2H_2O$) usually contains less than 2% alkalis and smaller quantities of iron, lime, magnesium, and titanium. Because of its purity, kaolin has a high fusion point and is the most refractory of all clays. Lone kaolins are widely used in casting sanitary ware, ceramics, and refractories.

Georgia china clay is one of the most uniform kaolins to be found. Generally speaking, there are two types of Georgia-sourced kaolin, both of which are widely used for casting and other processes. One type imparts unusually high strength and plasticity and is used for both casting and jiggering where a high degree of workability is required. The other type typically is a fractionated controlled particle size clay that also behaves well in casting, dries uniformly, and reduces cracking of ware.

Calcined Kaolin

This commercial product is made from a specially prepared kaolin that is low in iron and alkalis. Analyses show the calcined product to be principally mullite ($3Al_2O_3 \cdot 2SiO_2$) in association with an amorphous siliceous material. In fact, of the alumina present, 96% is converted to mullite. Iron content is not only low but in such a state of oxidation as to facilitate solid solution with the alumina.

Outstanding properties of refractories containing this calcined kaolin are high refractoriness and retention of shape under load; a high resistance to corrosion by slags, glasses, and glaze or enamel frits; resistance to thermal shock; and high mechanical strength.

It is being used in thermal shock bodies, refractories subjected to reducing atmospheres, kiln furniture compositions, thermal insulation bodies, low-expansion bodies, permeable ceramic compositions, high-temperature castables, and investment molds for precision casting; as a placing medium, as a kiln wash, and as gripping sand for high-tension insulators; and in many other special refractory applications.

The *Cornwall kaolin* of England and the *Limoges kaolin* of France are the best known. English china clays contain little or no iron oxide, and the yellow clays contain only organic materials that can be bleached out. The best grades of English clay are used for coating and filling paper. Cornish clay, known as *china stone*, is used for the best grades of porcelain glazes. Cheaper grades of kaolin, called *mica clay*, are used for earthenware glazes and as an absorbent and oil purifying. *Kaolin fiber* of extreme fineness, with average diameter of 118 μ in. (3 μ m), is made from kaolin containing about 46% alumina, 51% silica, and 3% iron and titanium oxide. It withstands continuous temperatures to 2000°F (1093°C). Kaowool, of Babcock and Wilcox, is kaolin fiber in the form of insulating blankets, and *kaolin paper* is made from the fibers compressed to thicknesses up to 0.08 in. (0.20 cm) with or without a binder. It withstands temperatures of up to 2000°F (1093°C) and is used for filters, separators, and gaskets.

Kapok

A silky fiber obtained from the seed pods of the silk-cotton trees, now grown in most tropical countries. It is employed for insulation and fine padding work. It is extremely light and resilient. The chemical constituents are the same as those of jute, but the proportions are different. Kapok is low in alpha cellulose, 43%, and high in pentosans, 24%; lignin, 15%; and uronic anhydride, 6.6%. Most of the commercial kapok normally comes from Java.

Karat

A unit for designating the fineness of gold in an alloy. In this system, 24 karat (24k) is 1000 fine or pure gold. The most popular jewelry golds are as follows:

Karat Designation	Gold Content
24k	100% Au (99.95% min)
18k	18/24th, or 75% Au
14k	14/24th, or 58.33% Au
10k	10/24th, or 41.67% Au

Keel Block

A standard test casting, for steel and other shrinkage alloys, consisting of a rectangular bar that resembles the keel of a boat, attached to the bottom of a large riser, or shrinkhead. Keel blocks that have only one bar are often called Y blocks; keel blocks having two bars,

K

double keel blocks. Test specimens are machined from the rectangular bar, and the shrinkhead is discarded.

Keeper

A piece of magnetically soft iron set across the poles of a permanent magnet to close the magnetic circuit and hence preserve the magnetism.

Keller's Etch

2.5 mL nitric acid, 1.5 mL hydrochloric acid, 1 mL hydrofluoric acid, and 100 mL water. Used for aluminum alloys.

Kelvin

A scale of absolute temperatures in which zero is approximately -273.16°C (-459.69°F). The color temperature of light is measured in kelvins. See *absolute temperature*.

Kelvin Effect

The electromotive force produced by a difference of temperature between two sites of a conductor and the release or absorption of heat associated with an electrical current flowing between two sites on the conductor that are at different temperatures. See also *thermoelectric effect*.

Kennedy Friction

Friction under conditions of macroscopic relative motion between two bodies. This term is sometimes used as a synonym for *kinetic coefficient of friction*; however, it can also be used merely to indicate that the type of friction being indicated is associated with macroscopic motion rather than static conditions.

Kerf

The width of a saw cut or other gap left when material has been cut away. Also *the cut face*.

Kerosene

Originally the name of illuminating oil distilled from coal, and also called *coal oil*. It is now a light, oily liquid obtained in the fractional distillation of petroleum. It is distilled off after gasoline between the limits of 345°F and 550°F (174°C and 288°C). It is a hydrocarbon with a composition $\text{C}_{10}\text{H}_{22}$ to $\text{C}_{16}\text{H}_{34}$, with a specific gravity between 0.747 and 0.775. Kerosene is employed for illuminating and heating purposes, as a fuel in internal combustion engines, and for turbine jet fuels. The heaviest distillate, known as *range oil*, is sufficiently volatile to burn freely in the wick of a heating range, but not as volatile as to be explosive. It is nearly free from odor and smoke. *Deodorized kerosene*, used in insect sprays, is a kerosene highly refined by treatment with activated earth or activated carbon. *Fialasol* is a *nitrate kerosene* used as a solvent for the scouring of wool. It is less flammable and has a slower rate of evaporation than kerosene, and it is odorless.

Kettle

A small vessel with a loose top in which small quantities of low-melting-temperature metals are melted.

Kevlar

An organic polymer composed of aromatic polyamides (*aramids*) having a paratype orientation (parallel chain with bonds extending from each aromatic nucleus). Often used as a reinforcing fiber. It has high tensile strength and elastic modulus, making it particularly suitable for reinforcement of composites. The term is also loosely used of the composite material containing the Kevlar fiber.

Key

(1) In a metallurgical context, this term refers to the ability of a surface to provide good adhesion for paint or other coatings. The key may be improved by mechanical means such as abrading or shot blasting or by chemical treatment. (2) A piece of material set longitudinally, half and half, and the interface between, typically, a shaft and a body mounted on it. It is inserted in the keyways in the two components to maintain location or provide drive.

Keyhole

A technique of welding in which a concentrated heat source, such as a plasma arc, penetrates completely through a workpiece forming a hole at the leading edge of the molten weld metal. As the heat source progresses, the molten metal fills in behind the hole to form the weld bead.

Keyhole Notch

A notch, in an impact test specimen, which has a narrow neck at the surface and terminates within the material and a round hole. The fracture is intended to initiate at the hole opposite the neck.

Keyhole Specimen

A type of specimen containing a hole-and-slot notch, shaped like a keyhole, usually used in impact bend tests. See also *Charpy test* and *Izod test*.

k-Factor

The ratio between the unknown and standard x-ray intensities used in quantitative analyses.

Kikuchi Lines

Light and dark lines superimposed on the background of a single-crystal electron diffraction pattern caused by diffraction of diffusely scattered electrons within the crystal: the pattern provides structural information on the crystal.

Kill/Killing

See *killed steel*.

Killed Spirits

Saturated solution of zinc chloride used as a soldering flux.

Killed Steel

(1) Usually, a steel that has been fully deoxidized with a strong deoxidizer such as silicon, manganese, or aluminum preventing any

reaction between carbon and oxygen during solidification. (2) Less commonly than (1), a steel that has been lightly worked to eliminate the pronounced yield point that gives rise to Lüders lines. See *capped steel*.

Kiln

(1) Any vessel or enclosed space in which some heating process is carried out. Choice between “kiln,” “oven,” and “furnace” is more a matter of preference in the industry concern rather than any consistent technical difference. It is used for baking, drying, or burning firebrick or refractories or for calcining ores or other substances.

Kiloelectron Volt (keV)

A unit of energy usually associated with individual particles. The energy gained by an electron when accelerated across 1000 V.

Kinematic Viscosity

See *viscosity*.

Kinematic Wear Marks

In ball bearings, a series of short curved marks on the surface of a bearing race due to the kinematic action of embedded particles or asperities rolling and spinning at the ball or roller contact points. The length and curvature of these marks depend on the degree of spinning and on the distance from the spinning axis of the rolling element.

Kinetic Coefficient of Friction

The *coefficient of friction* under conditions of macroscopic relative motion between two bodies.

Kinetic Energy

The energy that a body possesses because of its motion; in classical mechanics, equal to one-half of the body's mass times the square of its speed.

Kinetic Theory

At a temperature of absolute zero, atoms and molecules are at rest. As the temperature rises, the atoms and molecules absorb energy in which they retain as kinetic energy associated with their vibration. As the energy increases, the atoms and molecules vibrate increasingly until at some stage they are able to flow over each other, that is, the material becomes liquid. Further increase in energy and vibrations allow individual atoms or molecules to escape from the bulk, that is, the material becomes a gas. The impact of the vibrating atoms on the containment is manifested as pressure.

Kingsbury Bearing

See *tilting-pad bearing*.

Kink Band (Deformation)

In polycrystalline materials, a volume of crystal that has rotated physically to accommodate differential deformation between

adjoining parts of a grain while the band itself has deformed homogeneously. This occurs by regular bending of the slip lamellae along the boundaries of the band. Deformation bands associated with slip on multiple parallel crystallographic planes.

Kirkendall Voids

The formation of voids by diffusion across the interface between two different materials, with the material having a greater diffusion rate diffusing into the other.

K_{ISCC}

Abbreviation for the critical value of the plane strain *stress-intensity factor* that will produce crack propagation for *stress-corrosion cracking* of a given material in a given environment.

Kish

Free graphite that forms in molten hypereutectic cast iron as it cools. In castings, the kish may segregate toward the cope surface, where it lodges at or immediately beneath the casting surface and it is very weakening.

Klystron

An evacuated electron-beam tube in which an initial velocity modulation imparted to electrons in the beam subsequently results in density modulation of the beam. This device is used as an amplifier or oscillator in the microwave region.

Knee (Resistance Welding)

The lower arm supporting structure in a resistance welding machine.

Knife Coating

A method of coating a substrate (usually paper or fabric) in which the substrate, in the form of a continuous moving web, is coated with a material, the thickness of which is controlled by an adjustable knife or bar set at a suitable angle to the substrate.

Knife-Line Attack

Intergranular corrosion of an alloy, usually stabilized stainless steel, along a line adjoining or in contact with a weld after heating into the sensitization temperature range. Local attack in the heat-affected zone of welds in some austenitic stainless steels. Similar to weld decay except that it is located in the temperature zone that closely approaches the solidus.

Knitted and Woven Metals

Although they are commonly referred to in some context and are used for some of the same applications, there is a considerable difference between knitted and woven metals. As their name implies, knitted metals are knitted into a mesh structure in much the same way as stockings or sweaters. The structure of woven wire, on the other hand, is usually simpler, consisting of interwoven strands of wire. Whereas weaving usually produces a symmetrical mesh, usually with square openings and parallel wires, knitting produces an asymmetrical mesh of interlocking loops.

K

Knitted Metals

An important advantage of knitting is that it produces a mesh of interlocking loops, each of which acts as a small spring and provides resiliency. Because of this resiliency, knitted metals are usually able to withstand greater loads and deflections without being permanently deformed.

Knitted wire also has both a large surface area and a high percentage of free space. Thus, knitting permits construction of a mesh using wire with a maximum surface area and with interstices of almost any desirable size, regardless of wire diameter. Fine wire, for example, has been knitted into a mesh with as few as 3–5 openings to the inch.

The free volume of knitted wire can be controlled between 50% and 98%, depending on the interstice size, and regardless of the wire size used. Even when the wires are widely spaced to produce a potential volume of 98%, the structure retains its shape; a similar spacing with woven wire would result in a shape that would be almost impossible to handle.

Another important property of knitted metals is their ability to maintain their dimensions during temperature cycling. When the meshes are slightly stretched in every direction and expansion occurs, the sides of the loops are merely forced closer together without changing the overall dimensions of the plane of the surface.

Knitted metals can be produced in wire dimensions of 0.01–0.6 mm in such materials as steel, copper, brass, aluminum, stainless steel, and various nickel alloys including Monel. In fact, almost any metal that can be drawn into wire can be knitted. Thus, knitted parts can be made in a wide range of strength, corrosion resistance, wear resistance, electrical shielding, and heat resistance properties.

The asymmetrical mesh of knitted parts is advantageous for electronic shielding because the continuous-loop structure apparently causes induced currents to cancel themselves. Apart from this application, however, the biggest use for knitted wire is to remove one material from another. Thus, it can be used to separate two phases of the same material, to separate two admissible liquids, or to separate a solid from a liquid or a gas. The degree of separation can be controlled by varying the compression used to form or shape the knitted part and by controlling the size and shape of the wire and the size of the loops.

A good example of this kind of application is a mist eliminator in which the knitted mesh separates the liquid phase from the gas phase. Gases bearing droplets from such processes as distillation, evaporation, scrubbing, cleaning, or absorption are passed through built-up layers of knitted fabrics of up to 152 mm thick. The droplets collect on the loops and slowly run to the bottom where they accumulate. Liquid particles as small as 5–20 μm can be separated with efficiencies as high as 98%–100%. Although small eliminators are usually made in one piece, eliminators can be made up to 8.4 m in diameter by building up layers of crimped mesh.

Knitted metals are also used in many other applications where their special structure and properties are useful. Fuel line filters, for example, of knitted wire are resilient and do not require precise machining for sidewall fit. Gaskets of knitted wire have excellent conductivity and sufficient resiliency to produce tight joints on uneven surfaces, thereby preventing radio frequency leakage. Heat dissipation sleeves of knitted metal for subminiature glass tube envelopes provide high cooling efficiency. Knitted metals also provide good shock and vibration control when used as mountings for airborne and industrial equipment.

Woven Metals

Woven wire cloth is used in a wide range of applications for grading materials, filtering, straining, washing, guarding, reinforcing, and

decorating. A variety of meshes in different materials and sizes is available to meet these applications.

Like knitted wire, woven wire cloth can be produced in almost any metal that can be drawn into wire, including carbon and stainless steel, copper, brass, bronze, nickel, Monel, Inconel, and aluminum. Plain steel wire cloth is one of the most economical and generally used materials. However, it may require a protective coating to prevent rusting.

Corrosion can be prevented by using tinned or galvanized wire; tinned wire is preferred for handling food products, galvanized for all other applications. Where required, the cloth can also be provided with a protective electroplate of cadmium, chromium, or tin. Phosphate coatings and paints can also be used.

Where severe corrosion conditions are encountered, the weave can be made from such materials as stainless steel, Monel, phosphor bronze, and silicon bronze; some of these materials are available only in limited sizes. Abrasive-resistant steels are available for applications where abrasive materials have to be handled. Many grades of stainless can also be used to withstand high temperatures, for example, 347 stainless (up to 760°C), 309 and 310 (up to 871°C), and 310 stainless as well as Inconel and nichrome (up to 1003°C).

Woven wire cloth is widely used for filtering and straining, particularly in automotive and aviation applications for carburetors, air screens, and oil and fuel strainers. They are also used to grade materials and for wire baskets, insect screening, and safety guards.

Knitted Fabrics

Fabrics produced by inner looping chains of yarn.

Knock

In a spark ignition engine, uneven burning of the air/fuel charge that causes violent, explosive combustion and an audible metallic hammering noise. Knock results from premature ignition of the last part of the charge to burn.

Knockout

(1) Removal of sand cores from a casting. (2) Jarring of an investment casting mold to remove the casting and investment from the flask. (3) A mechanism for freeing formed parts from a die used for stamping, blanking, drawing, forging, or heading operations. (4) A partially pierced hole in a sheet metal part, where the slug remains in the hole and can be forced out by hand if a hole is needed.

Knockout Mark

A small protrusion, such as a button or ring of flash, resulting from depression of the *knockout pin* from the forging pressure or the entrance of metal between the knockout pin and the die.

Knockout Pin

A power-operated plunger installed in a die to aid removal of the finished forging.

Knockout Punch

A punch used for ejecting powder compacts.

Knoop Hardness Number (HK)

A number related to the applied load and to the projected area of the permanent impression made by a rhombic-based pyramidal diamond indenter having included edge angles of $172^{\circ}30'$ and $130^{\circ}0'$ computed from the equation

$$HK = \frac{P}{0.07028d^2}$$

where

P is the applied load, kgf

d is the long diagonal of the impression, mm

In reporting Knoop hardness numbers, the test load is stated. See *hardness test*.

Knoop Hardness Test

An indentation hardness test using calibrated machines to force a rhombic-based pyramidal diamond indenter having specified edge angles, under specified conditions, into the surface of the material under test and to measure the long diagonal after removal of the load.

Knuckle Area

In reinforced plastics, the area of transition between sections of different geometry in a filament-wound part, for example, where the skin joins the cylinder of the pressure vessel. Also called Y joint.

Knuckle-Lever Press

A heavy short-stroke press in which the slide is directly actuated by a single toggle joint that is opened and closed by a connection and crack. It is used for embossing, coining, sizing, heading, swaging, and extruding.

Knurling

Impressing a design into a metallic surface. A pattern of deep indentations, typically a diamond grid and similar in appearance to a file face, formed on a surface, usually cylindrical, to improve grip. The effect is achieved by forcing hard rollers, machined to the required pattern, against the rotating surface.

K Radiation

Characteristic x-rays produced by an atom or ion when a vacancy in the K shell is filled by an electron from another shell.

Kraft Process

A wood-pulping process in which sodium sulfate is used in the caustic soda pulp-digestion liquor. Also called kraft pulping or sulfate pulping.

Kroll Process

A process for the production of metallic titanium sponge by reduction of titanium tetrachloride with a more active metal, such as magnesium or sodium. The sponges are further processed to granules or powder.

K-Series

The set of characteristic x-ray wavelengths making up K-radiation for the various elements.

K Shell

The innermost shell of electrons surrounding the atomic nucleus, having electrons characterized by the principal quantum number 1.

Krypton

An element, one of the inert gases.

Kyanite

A natural aluminum silicate, $Al_2O_3 \cdot SiO_2$, used as a refractory especially for linings of glass furnaces and furnaces for nonferrous metals. Molded or cast ceramic parts having nearly 0 thermal expansion up to $2300^{\circ}F$ ($1260^{\circ}C$). It is a common material but occurs disseminated with other minerals and is found in commercial quantities and grades in only a few places. Most of the world production has been in eastern India, but high-grade kyanite is now obtained from Kenya. It is also mined in North Carolina, Georgia, Virginia, and California. Low-grade kyanite is used in glassmaking as a source of alumina to increase strength and chemical and heat resistance. Aluminosilicate materials are widely distributed in nature combined in complex forms, and the aluminosilicate extracted from them is called *synthetic*. Kyanite powder, produced from Florida beach sands, has round, single-crystal grains of kyanite and sillimanite in nearly equal proportions. The beach sands are screened and graded and marketed as granules of various sizes for compacting and sintering into refractory ceramic parts.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

L_{10} -Life

See *rating life*.

Labile

Unstable.

Laboratory Sample

A sample, intended for testing or analysis, prepared from a gross sample or otherwise obtained; the laboratory sample must retain the composition of the gross sample. Reduction in particle size is often necessary in the course of reducing the quantity.

Lack of Fusion (of Weld)

The absence of the intended fusion bond in which fusion is less than complete.

Lack of Penetration (LOP)

A condition in a welded joint in which joint penetration is less than that specified.

Lack of Resin Fill-Out

In reinforced plastics, a condition in which an area contains reinforcement not wetted with a sufficient quantity of resin. This condition usually occurs at the edge of a pultrusion.

Lacquer

(1) A coating formulation based on thermoplastic film-forming material dissolved in organic solvent. The coating dries primarily by evaporation of the solvent. Typical lacquers include those based on lac, nitrocellulose, and other cellulose derivatives, vinyl resins, acrylic resins, and so forth. (2) In lubrication, a deposit resulting from the oxidation and/or polymerization of fuels and lubricants when exposed to high temperatures. Softer deposits are described as varnishes or gums.

Ladder Polymer

A polymer with two polymer chains cross-linked at intervals.

Ladle

A vessel for transporting molten metal from one stage to the next, particularly from the melting furnace to the mold. It may range from a handheld "spoon" to very large mechanized or crane-carried vessels holding many tons of metal. Types include hand, bull, crane, bottom-pour, holding, teapot, shank, and lip-pour.

Ladle Addition/Treatment/Process

Processes for the final refinement and composition control of metal before it is cast, particularly treatment in a ladle or holding bath with no additional heating.

Ladle Brick

Refractory brick suitable for lining ladles used to hold molten metal.

Ladle Coating

The material used to coat metal ladles to prevent iron pickup in aluminum alloys. The material can consist of sodium silicate, iron oxide, and water, applied to the ladle when it is heated.

Ladle Metallurgy

Degassing processes for steel carried out in a *ladle*.

Ladle Preheating

The process of heating a ladle prior to the addition of molten metal. This procedure reduces metal heat loss and eliminates moisture-steam safety hazards.

Lagging

Thermal insulation particularly when it is applied on the exterior of the vessel being protected rather than on the interior and in contact with the reaction environment.

Lamella

The basic morphological unit of a crystalline polymer, usually ribbonlike or platelike in shape. Generally, about 10 mm thick, 1 μm long, and 0.1 μm wide, if ribbonlike.

Lamellae

Multiple thin plates stacked as laminations.

Lamellar Corrosion/Attack

The loss of material, as layers, from a metal surface. Corrosion proceeds along a plane just below and parallel with the surface and the release layer is substantially uncorroded. The term *exfoliating corrosion* is usually applied to cases where the sheets of material released are entirely or predominantly corrosion product. See *exfoliation corrosion*.

L

Lamellar Cracking/Tearing Cracking

This cracking of rolled products such as plate or bar, can lie beneath and parallel with the surface. It usually follows planes of weakness, particularly areas of nonmetallic inclusions, introduced at the original casting stage and deformed to a planar form during rolling. The planes of weakness have little effect on the longitudinal or transverse strength but considerably reduce the strength in the through-thickness direction. Loads acting in this direction are imposed when a weld is applied to the surface of a plate or bar. The initial defect can develop as a result solely of the stresses introduced by the welding operation and in this case they will often be confined to the parent metal beneath the weld. However, when a service load is applied the cracks are likely to propagate leading to failure. See also *cold cracking*, *hot cracking*, and *stress-relief cracking*.

Lamellar Thickness

A characteristic morphological parameter in plastics, usually estimated from x-ray studies or electron microscopy, which is usually 10–50 nm. The average thickness of lamellae in a specimen. See also *lamella*.

Lamina

A single ply or layer in a laminate, which is made up of a series of layers.

Laminar Flow

The flow of plastic resin in a mold, characterized by solidification of the first layer to contact the mold surface, which then acts as an insulating tube through which material flows to fill the remainder of the cavity. This type of flow is essential to duplication of the mold surface. The movement of this fluid stream is such that no lateral intermixing occurs, effectively *streamline flow*.

Laminate

To unite laminate with a bonding material, usually with pressure and heat (normally refers to flat sheets, but also includes rods and tubes); a product made by such bonding. Two or more layers of material bonded together. The term can apply to preformed layers joined by adhesives or by heat and pressure. The term also applies to composites of plastic films with other films, or with foil or paper, even though they have been made by spread coating or by extrusion coating. A reinforced laminate usually refers to superimposed layers of resin-impregnated or resin-coated fabrics or fibrous reinforcements that have been bonded, especially by heat and pressure. Products produced with little or no pressure, such as hand layups, filament-wound structures, and spray-ups, are sometimes called contact-pressure laminate. A single resin-impregnated sheet of paper, fabric, or glass mat is not considered a laminate. Such a single-sheet construction may be called a *lamina*. See also *bidirectional laminate*, *cross laminate*, *parallel laminate*, and *unidirectional laminate*.

Laminate Coordinates

A reference coordinate system used to describe the properties of a laminate, generally in the direction of principal axes, when they exist.

Laminate Orientation

The geometric configuration of a cross-plyed composite laminate with regard to the angles of cross-plying, the number of laminae at each angle, and the exact sequence of laminae layup.

Laminate Ply

One fabric-resin or fiber-resin layer (of a product) that is bonded to adjacent layers in the curing process.

Laminate Void

The absence of resin in an area that normally contains resin.

Laminated Glass

Two or more glasses that are fused together to produce a material with properties that would have been either difficult or impossible to obtain in a single glass. There are many multistep lamination processes. Usually, a glass is formed during one process and is subsequently laminated with another glass during a separate process that involves melting the two glasses in separate furnaces and then passing them through a cladding delivery system.

Laminated Plastics

Laminated plastics are a special form of polymer matrix composites (PMC) consisting of layers of reinforcing materials that have been impregnated with thermosetting resins, bonded together, and cured under heat and pressure. The cured laminates, called high-pressure laminates, are produced to more than 70 standard grades.

Laminated plastics are available in sheet, tube, and rod shapes that are cut or machined for various end uses. The same base materials are also used in molded-laminated and molded-macerated parts. The molded-laminated method is used to produce shapes that would be uneconomical to machine from flat laminates, where production quantities are sufficient to warrant mold costs.

Strength of a molded shape is higher than that of a machined shape because the reinforcing plies are not cut as they are in a machined part. The molded-macerated method is used for similar parts that require uniform strength properties in all directions.

Other common forms of laminated plastics are composite sheet laminate that incorporate a third material bonded to one or both surfaces of the laminate. Metals most often used in composites are copper, aluminum, nickel, and steel. Copper-clad sheets (one or both sides) for printed-circuit and multilayer boards comprise the largest volume of metal composite sheet laminate. Nonmetallics include elastomers, vulcanized fiber, and cork. Composite metal/plastic materials are also produced in rods and tubes.

Vulcanized fiber is another product often classified with the laminated plastics because end uses are similar. Vulcanized fiber is made from regenerated cotton cellulose and paper, processed to form a dense material (usually in sheet form) that retains the fibrous structure. The material is tough and has good resistance to abrasion, flame, and impact.

Phenolics are the most widely used resin in laminated plastics. These low-cost resins have good mechanical and electrical properties and resistance to heat, flame, moisture, mild acids, and alkalis. Most paper- and cloth-reinforced laminates are made with phenolics.

Lamination

(1) A type of discontinuity with separation or weakness generally aligned parallel to the work surface of the metal. May be the result of pipe, blisters, seams, inclusions, or segregation elongated and made directional by working. Laminations may also occur in powder metallurgy compacts. (2) Generally, any sheets intended for assembly as a pile. More particularly, varnished (for insulation) steel sheets piled and clamped together to form the core of transformers, generator stators, and some rotors. This construction, together with the use of special steels minimizes iron loss.

Lampblack

A soot formed by the smudge process of burning oil, coal tar, resin, or other carbonaceous substances in an insufficient supply of air, the soot being allowed to settle on the walls or floors of the collecting chambers. Lampblack is practically pure carbon, but inferior grades may contain unburned oil. It is chemically the same as carbon black made from gas, but since it may contain as high as 2.5% oil, it is not generally used in rubber. The particle size is large, 2559–3937 $\mu\text{in.}$ (65–100 μm), and the pH is low, 3–3.5. However, some *amorphous carbons*, made from either tar oil or crude oil by spraying the oil and air into a close retort at 3000°F (6049°C) to obtain partial combustion, are equal to carbon black for many uses. Lampblack is used in making paints, lead pencils, metal polishes, electric brush carbons, crayons, and carbon papers. Carbon brushes for use in electric machinery are made by mixing lampblack with pitch. Petroleum coke or graphite is added to impart special properties. For special arc lights, a mixture of lampblack, rare-earth oxides, fluorides, and coal as a binder is extruded. The combination of rare earths determines the type of radiation emitted. It is grayish black, flaky, and granular. The color is not as intensely black as carbon black. *Lampblack oil* is a coal-tar product marketed for making lampblack.

Fine soot used in the reduction and carburization of tungsten trioxide and titanium dioxide to produce tungsten carbide and titanium carbide powder, respectively.

Lampworking

Forming glass articles from tubing and cane by heating in a gas flame.

Lance

A tube directing some fluid onto a process vessel.

Lancing

(1) A press operation in which a single-line cut is made in strip stock without producing a detached slug. Chiefly used to free metal for forming, or to cut partial contours for blank parts, particularly in progressive dies. (2) A misnomer for *oxyfuel gas cutting*.

Land (Metals)

(1) For profile-sharpened milling cutters, the relieved portion immediately behind the cutting-edge. (2) For reamers, drills, and taps, the solid section between the flutes. (3) On punches, the portion adjacent to the nose that is parallel to the axis and of maximum diameter. (4) A flat surface on component, particularly one machined to provide a seat or similar function.

Land (Plastics)

(1) The horizontal bearing surface of a semi-positive or flash mold by which excess material escapes. (2) The bearing surface along the top of the flights of a screw in a screw extruder. (3) The surface of an extrusion die parallel to the direction of melt flow. (4) The land region of a nozzle used in injection molding.

Lang's Lay

One of the more common systems of laying, that is, assembling, the individual fibers or wires forming each strand of a multi-strand rope or cable. In essence all wires and strands follow the same twist direction.

Langelier Saturation Index

An index calculated from total dissolved solids, calcium concentration, total alkalinity, pH, and solution temperature that shows a tendency of a water solution to precipitate or dissolve calcium carbonate.

Lanthanides

The rare earth metallic elements with atomic numbers 57 (lanthanum) to 71.

Lanthanum

A chemical element, lanthanum, symbol La, the second most abundant element in the rare earth group, is a metal. The naturally occurring element is made up of the isotopes and is one of the radioactive products of the fission of uranium, thorium, or plutonium. Lanthanum is the most basic of the rare earths and can be separated rapidly from other members of the rare earth series by fractional crystallization. Considerable quantities of it are separated commercially, because it is an important ingredient in glass manufacture. Lanthanum imparts a high refractive index to the glass and is used in the manufacture of expensive lenses. The metal is readily attacked in air and is rapidly converted to a white powder.

Lanthanum becomes a superconductor below about -267°C in both the hexagonal and face-centered crystal forms.

Lanthanum Oxide

Lanthanum oxide (La_2O_3) has a melting point of 2250°C , and is soluble in acids, and very slightly soluble in water. This oxide of a rare earth element occurs in monazite and bastnasite. It is marketed as the oxide or as other salts such as the oxalate, nitrate, or hydrate. It quickly absorbs water and carbon dioxide from the atmosphere.

Its chief use is as an ingredient in nonsilica, rare earth optical glass with oxides of tungsten, tantalum, and thorium. Lanthanum increases refractive index, decreases dispersion, and is also used in x-ray image intensifying screens that speed up x-ray exposure as much as 2–10 times so that diagnostic dosages may be reduced by as much as 80% with fewer retakes. It is also used in barium titanate capacitors.

Lanxide Process

A composite material formation process that involves pressureless metal infiltration into a ceramic preform. The molten metal is exposed to an oxidizing atmosphere resulting in a matrix material

composed of a mixture of the oxidation reaction product and unreacted metal.

Lanxides

A composite formed in the reaction between a molten metal and oxygen in air to some other vapor-phase oxidant. Normally, such a situation produces an unwelcome scum on the surface of the metal. However, by controlling the temperature of the molten metal and by adding traces of suitable dopant metals, an inch/cm-thick layer of a metal oxide composite can be grown on the surface of the liquid. Composites up to 10 cm thick and weighing up to 18 kg have been grown by this method, with no falling off in growth rate. Under the right conditions, a lanxide composite is considerably stronger than sintered alumina. This makes such a composite potentially useful for armor plating, rocket or jet engines, and other applications.

Lap (Composites)

(1) In filament winding, the amount of overlay between successive windings, usually intended to minimize gapping. (2) In adhesive bonding, the distance one adherend covers another adherend.

Lap (Metals)

(1) A surface imperfection, with the appearance of a seam, caused by hot metal, fins, or sharp corners being folded over and then being rolled or forged into the surface but without being welded. (2) A planar manufacturing defect, either a small cold shut from casting or a fold, produced during some working operation that has been flattened but not welded or bonded. (3) A polishing pad carrying embedded abrasives.

Lap (Shear) Test

A tensile test in the plane of the parent plates of a lap joint so that the load is carried by the full joint, as opposed to peel test.

Lap Joint

The joint formed between two overlapping components such as plate or sheet. The joint may be affected by riveting, brazing, or various welding techniques, including spot welding through the interface or fillet welding the internal corner between edge and face.

Lapping

A finishing operation using fine abrasive grits loaded into a lapping material such as cast iron. Lapping provides major refinements in the workpiece, including extreme accuracy of dimension, correction of minor imperfections of shape, refinement of surface finish, and close fit between mating surfaces.

Large-End Bearing

See *big-end bearing*.

Larmor Frequency

The classical frequency at which a charged body precesses in a uniform magnetic field. $\omega_L = -eB/2mc$, where e is the electron charge,

B is the magnetic field intensity, m is mass, and c is the velocity of light. See also *Larmor period*.

Larmor Period

The inverse of the Larmor frequency. See also *Larmor frequency*.

Larson Miller Parameter

An empirical relationship for predicting the complete range of creep rupture properties of a material on the basis of a limited number of tests. Creep life is a function of stress and temperature and, for a particular material at a fixed stress, the parameter P is given:

$$P = T(c + \log t)$$

where

T is the temperature in degrees absolute

t is the time to failure

c is a constant for each material

Normal practice is to undertake a series of tests over a fairly broad range of stress levels and plot the P value against the logarithm of the stress. This produces a smooth curve, which can be correlated with rupture life and temperature. Thus when any two variables are specified, the third can be deduced. For example, a designer might need to know the maximum stress allowable to achieve a life of 10,000 h at 500°C for the material in question. To determine this, a horizontal line is drawn across at the 500°C level to intersect the 10,000 line and from this intersection a vertical line is drawn down to intersect the P curve. A Z line drawn horizontally from the P line intersects across the stress scale at the allowable stress.

Laser

Laser Alloying

This is a material processing method that utilizes the high power density available from focused laser sources to melt metal coatings and a portion of the underlying substrate. Since the melting occurs in a very short time and only at the surface, the bulk of the material remains cool, thus serving as an intimate heat sink. Large temperature gradients exist across the boundary between the melted surface region and the underlying solid substrate. The result is rapid self-quenching and resolidification.

Transitions

The sequence in the transitioning that occurs during and following an individual laser exposure. Initially, the metal substrate (B) is coated with a thin metal foil (A) and is irradiated with a laser pulse. For metal surfaces and most laser wavelengths, a significant fraction of the incident light will be specularly or diffusely scattered away. The absorbed energy is "instantaneously" (10^{-12} s) transferred to the lattice. The near-surface region very rapidly reaches the melting point, and a liquid-solid interface starts to move through the film. The liquid-solid interface has swept through the original thin-film-substrate interface. Interdiffusion of the film and substrate elements starts. The laser pulse is nearly terminated, and the surface has remained below the vaporization temperature. At this point, the maximum melt depth has been reached, and interdiffusion continues. The resolidification interface velocity is momentarily zero and then rapidly increases. The resolidification interface has moved approximately halfway back to the surface from the melt depth.

Interdiffusion into the liquid continues, but the re-solidified metal behind the liquid–solid interface cools so rapidly that solid-state diffusion may be neglected. Finally, the material is completely resolidified, and a “surface alloy” has been produced.

What makes laser surface alloying both attractive and interesting is the wide variety of chemical and microstructural states that can be retained because of the rapid quench from the liquid phase. These include chemical profiles where the “alloyed” element A is highly concentrated near the atomic surface and decreases in concentration over shallow depths (hundreds of nanometers), and uniform profiles where the concentration of A in B is the same throughout the entire melted region. The types of microstructures observed include extended solid solutions (the concentration of A in B greatly exceeds equilibrium values), metastable crystalline phases (high-temperature phases retained because of the rapid return to room temperature), and metallic glasses.

For a pulsed or Q-switched laser (high-power, short-pulse laser) source, there also is an optical and effective spot size, and the “pulse length” is the time of exposure. The laser pulses are emitted in a train of pulses characterized by a repetition rate. For these lasers, the effective spot size, degree of overlap, and repetition rate determine the area per unit time that can be produced.

For all the laser sources (continuous-wave pulsed and Q-switched), the exposure time (dwell time or pulse length) strongly influences the depth that will be melted. Because deeper melting means a longer total time in the molten state, that means more time available for diffusion of the one or more alloying elements into the molten portion of the substrate. Deeper melting and longer melt times result in more dilute surface alloys, whereas shallow melting and shorter melt times result in more concentrated surface alloys. It is also evident that in some instances convection, surface tension, and plasma effects can enhance the mixing within the liquid state and drive the melt toward homogenization.

In making laser alloys, many other processing variables need to be considered. In addition to the exposure time just discussed, these include the laser power, the thickness of the film put down prior to laser melting, and in some instances the nature of the gaseous ambient during the laser processing. The processing variables are interrelated, and one variable cannot be freely changed without affecting another. Another consideration is that laser alloying is a liquid state-rapid quenching phenomenon. The near-surface region must be melted and yet vaporization avoided. Different minimum and maximum energy densities are thus defined for each laser exposure time. In addition to these processing constraints, there are certain properties of matter that strongly influence whether or not certain element combinations may be laser-alloyed. For example, it is not possible to laser-alloy a low-melting-point/high-vapor-pressure element like zinc into a high-melting-point/low-vapor-pressure metal substrate such as tungsten. The zinc would vaporize before the underlying tungsten could be melted. Because liquid-state intermixing is required, suitable systems must exhibit miscibility in the molten state. Binary systems like silver–nickel, iron–lead, copper–molybdenum and aluminum–bismuth have miscibility gaps in the liquid state spanning nearly all compositions. Such systems cannot be laser-alloyed.

Advantages

Surface alloys, particularly laser surface alloys, have advantages that include tailoring surface properties, conservation of materials, and creation of new metal surfaces.

Surface alloying allows alteration of the metal surface to achieve characteristics best suited to the surface environment. For example,

in an ordinary saw blade the material requirements for the cutting teeth are very different from those of the length of the blade. In many applications requiring corrosion or oxidation resistance, that resistance is needed only on the external surface of the material. It is possible to design the bulk of the material with characteristics most suitable for structural needs or ease of fabrication and to tailor the metal surface for interface requirements. Material conservation is another reason often cited for considering surface alloying. In the case of stainless steels and superalloys, the elements added to impart the special properties are often strategic elements for which there are sparse domestic supplies. For example, chromium and nickel may not be necessary on the inside of knives, forks, and spoons. Further, precious metals are expensive and in relatively short supply. Thus surface alloying can be very cost-effective.

These first two advantages—tailoring for surface properties and material conservation—are generally important considerations in almost any coating technology. However, laser alloying differs from coating technologies in that the near-surface region is a continuous extension of the interior of the metal. There is no interface between bulk and “coating” the laser alloy is a mixture of bulk and surface elements. Also, problems in regard to porosity and adherence do not exist.

Laser alloying involves very large temperature gradients and quenching from the liquid state. In this way, it resembles other rapid-solidification technologies.

It is anticipated that laser alloying will produce many new alloys that could not have been produced by conventional methods.

Laser Cooling

Reducing the thermal motion of atoms with the force exerted by a laser beam is laser cooling. Typically, such cooling is used to reduce the temperature of a gas of atoms, or the spread of atoms in an atomic beam.

The keys to using such repeated kicks to reduce the random, thermal motion of a gas of atoms are the monochromatic nature of laser light, the selectivity of absorption of light by atoms, and the Doppler effect.

The viscosity of laser cooling does not stop atoms. Although this might seem to be a fundamental limit, techniques have been developed that go even farther, by arranging that when, by chance, an atom achieves a very low velocity it stops absorbing light and remains cold. In this way, atoms have been cooled below the recoil limit.

Applications

Improving atomic clocks, where the thermal motion of atoms reduces the precision and accuracy, was a major motivation to developing laser cooling. Clocks using laser-cooled trapped ions or free natural atoms rival the performance of the best conventional atomic clocks. Laser cooling is also used in atom optics, where well-collimated, monoenergetic atomic beams are more easily and effectively manipulated. In addition, laser cooling has been used to study collisions between very slow atoms.

Laser Cutting

Types of Lasers for Metal Cutting

The continuous-wave (CW) CO₂ laser leads the way for metal cutting. The CW laser beam builds up in small-diameter gas-containing tubes with electrodes at each end. High-voltage direct current flows between electrodes, exciting gas atoms to develop the lasing effect.

The workhorse for metal cutting is the fast-axial-flow (FAF) CO₂ laser. The majority of these units are DC design, an economical laser excitation technique for cutting thin-gauge materials. The FAF laser produces a stable beam for high-quality cuts. Fast-flow technology moves gas rapidly through the discharge area to operate between 500 W and 6 kW. The fast flow efficiently cools the laser gas, making more power available in more compact units.

In the transverse flow (TF) CO₂ laser, gas flows in a transverse direction to the laser cavity axis. The laser gas circulates at high speed and cools through a heat exchanger. This design results in an output power in the 5–45 kW range. The TF laser produces a beam with a mixed mode for high-speed quality cuts. The compact TF design can enclose the laser in a workstation.

A solid-state laser describes an optically pure material that will lase when doped with specific elements. Neodymium-doped yttrium aluminum garnet (Nd:YAG) rates as the most popular solid-state laser for industrial use in either rod- or rectangular-shaped design.

Types of Cutting Machines

Flying-optics machines are systems that move the beam along the x - y axes and the workpiece is stationary. In the gantry design, a stationary workpiece improves positioning tolerances, especially for heavier workpieces. The space-efficient design and the unobstructed beam motion allow easy integration into production lines. Beam-motion accuracy holds constant over the entire working volume at 0.010 mm with a repeatability of 0.05 mm. Traverse rates can double other machine configurations.

The stationary head, or fixed-beam design, a widely used metal-cutting machine, integrates x and y workpiece motion and under a fixed-position laser beam. The beam design requires a minimum number of mirrors to bend the beam and maintain beam characteristics and quality over the travel distance.

The hybrid machine moves the workpiece in the x axis and the optics move in the y axis. To maintain beam accuracy, hybrid units offer shorter beam-delivery paths than full moving-beam systems. Moving the workpiece in only one axis permits more-accurate movement of heavier workpieces than with flying optics and holds position accurately to ± 0.010 mm and repeatability to ± 0.05 mm.

The advantages of cutting using robot-beam manipulation, the classic articulated arm with cylindrical or spherical coordinate designs, are obvious. Robots with internal optics for CO₂ laser cutting can cut very complex parts, but require good mechanics because the many joints and mirrors make alignment difficult. Fiber optics used to convey an Nd:YAG beam align more easily, but the minimum bending radius of the fiber can limit mobility. Units can hold 0.05 mm point-to-point repeatability, with dynamic path repeatability of 1 mm at 0.86 mm/s.

Laser Inspection

Laser inspection involves an inspection system in which lasers check that the soldering on printed circuit boards has been developed. The three-dimensional solder shape inspection machine detects faulty soldering by the non-contact three-dimensional shape measuring system. The system is based on laser measuring technology, and is said to provide accuracy 10 times higher than conventional technology in judging faulty soldering. The system reportedly also reduces the time required for preoperational arrangement to 1/10 that of normal.

The system utilizes a thin laser light 5 μ m thick, which scans the outline of solder paths on the principal board and compares the shape with a standard. Together with a high-speed camera, the system pictures the solder outline visualized through laser reflection from the solder surface, then processes the picture at a speed of

0.016 s/frame. The system then makes quantitative evaluation based on measured data about the size and the adhesion angle of the solder and the component height.

Laser Lithography

A line narrowed by 193 nm laser radiation has been demonstrated with 21 W output power. This is reportedly the highest ever demonstrated from a single-stage line narrowed argon-fluorine excimer laser oscillator.

The laser was operated with 1 kHz repetition rate and yielded more than 20 mJ/pulse with a bandwidth of less than 0.6 pm, FWHM. The achievement is a result of ongoing studies to improve the efficiency of the line narrowing resonator and laser tube design.

The argon-fluorine excimer lasers will likely be used for the next generation of deep ultraviolet lithography tools for semiconductor production of 1 Gbit memory chips and advanced microprocessors. Development efforts are underway to transfer the new technology into products suitable for 193 nm lithography production, particularly due to the reduced cost operation achievable.

Laser Peening

A laser peening method is being perfected that could significantly improve the durability of critical jet engine components. Although the laser peening concept is not new, a neodymium doped glass laser with 600 W of average power makes the process faster and economically feasible. The lasers capable of firing 10 pulses/s, compared with only 1 pulse every 2 s from commercial lasers. Laser peening, which uses concentrated light to generate a small, sudden force equivalent to about 30,000 times the pressure of the atmosphere, can leave a compressive residual stress in engine fan blades, disks, rotors, and shafts up to 1 mm deep. That is four times deeper than conventional shot peening. The compression significantly retards metal fatigue and corrosion, and improves damage tolerance.

Laser Alloying

See *laser surface processing*.

Laser Beam Cutting

(1) A cutting process that severs materials with the heat obtained from the application of a concentrated coherent light beam impinging upon the workpiece to be cut. The process can be used with (gas-assisted laser beam cutting) or without an externally supplied gas. (2) The cutting process utilizes a laser beam as a heat source. The high energy intensity of the focused beam facilitates deeply penetrating cuts and welds with minimum distortion. In the case of cutting, material is removed by some combination of melting with ejection of molten material and vaporization. Gas jet laser cutting utilizes an additional gas jet to assist ejection of molten material.

Laser Beam Machining

Use of a highly focused mono-frequency collimated beam of light to melt or sublime material at the point of impingement on a workpiece.

Laser Beam Welding

A welding process that joins metal parts using the heat obtained by directing a beam from a *laser* onto the weld joint.

Laser Hardening

A surface-hardening process that uses a laser to quickly heat a surface. Heat conduction into the interior of the part will quickly cool the surface, leaving a shallow martensitic layer.

Laser Surface Processing

The use of lasers with continuous outputs of 0.5–10 kW to modify the metallurgical structure of a surface and to tailor the surface properties without adversely affecting the bulk properties. The surface modification can take the following three forms. The first is transformation hardening in which a surface is heated so that thermal diffusion and solid-state transformations can take place. The second is surface melting, which results in a refinement of the structure due to the rapid quenching from the melt. The third is surface (laser) alloying, in which alloying elements are added to the melt pool to change the composition of the surface. The novel structures produced by laser surface melting and alloying can exhibit improved electrochemical and tribological behavior.

Latent Curing Agent

A curing agent for plastics that produces long-term stability at room temperature but rapid cure at elevated temperatures.

Latent Heat

Thermal energy absorbed or released when a substance undergoes a phase change.

Latent Heat of Fusion

Heat given off by a liquid freezing to a solid, or gained by a solid in melting to a liquid, without a change in temperature.

Latent Heat of Vaporization

Heat given off by a vapor condensing to a liquid, or gained by a liquid evaporating to a vapor, without a change in temperature.

Lateral Contraction

The contraction across the width and thickness of a material being loaded in tension. See *Poissons Ratio* and *anti-clastic*.

Lateral Crack

A crack produced beneath and generally paralleling a glass surface during the unloading phase of mechanical contact with a hard, sharp object. See also *cleavage crack*.

Lateral Extrusion

In operation in which the product is extruded sideways through an orifice in the container wall.

Lateral Runout

Same as *axial runout*.

Latex

The milklike juice of the rubber tree, now much used instead of the cured crude rubber for many rubber applications such as adhesives, rubber compounds, and rubber powder. The properties of latex vary with the type of tree, age of tree, method of tapping, and climate. Latex from young trees is less stable than that from old trees. Intensive tapping of the trees results in less rubber content, which may vary from 20% to 50%. For shipping, a preservative and anticoagulant are added to the latex, usually ammonia or sodium sulfate. Concentrated 60% latex is a stable liquid of cream like consistency. *Latex foam* is a cellular sponge rubber made by whipping air into latex, pouring into molds, and vulcanizing. *Artificial latex* is a water dispersion of reclaimed rubber. Water dispersions of crude or reclaim rubbers are produced by swelling and dissolving the rubber in an organic solvent, treating with an organic acid or with ammonia, and emulsifying. They resemble latex, but are softer and tackier and are used for adhesives. Latex foams are now usually made by incorporating a chemical, which releases a gas to form the cells.

The term *latex* now also refers to water dispersions of synthetic rubbers and rubberlike plastics. *Neoprene latex* is a water dispersion of neoprene rubber, and it has dispersed particles smaller than those of natural latex, giving better penetration including paper and textiles. Butadiene-styrene latex with 68% solids is used for producing foamed rubber. *Latex water paints* are now usually made with synthetic rubber or plastic dispersions.

Lath Martensite

Martensite formed partly in steels containing less than approximately 1.0% C and solely in steels containing less than approximately 0.5% C as parallel arrays of packets of lath-shape units 0.1–0.3 μm thick.

Lathe

A machine tool in which the workpiece is gripped in the rotating chuck and possibly supported at its far end by a tail stock. A lathe tool carried in the tool head of the saddle cuts the workpiece as the saddle travels along the bed or the tool head traverses the saddle.

Lattice

(1) A space lattice is a set of equal and adjoining parallelepipeds formed by dividing space by three sets of parallel planes, the planes in any one set being equally spaced. There are seven ways of so dividing space, corresponding to the seven crystal systems. The unit parallelepiped is usually chosen as the unit cell of the system. See also *crystal system* and *unit cell*. (2) A point lattice is a set of points in space located so that each point has identical surroundings. There are 14 ways of so arranging points in space, corresponding to the 14 Bravais lattices. See *7 crystal systems and corresponding 14 space Bravais lattices*. (3) The three-dimensional grid on which it is visualized, atoms are arranged in the crystal structure of solid metal.

Lattice Constants

See *lattice parameter*.

Lattice Construction/Girder, etc.

An assembly of slender girders, beams, etc., joined in a triangulated manner to provide a lightweight but high-strength construction.

L

Lattice Defects

Defects in the crystal structure such as dislocations, vacancies, and foreign atoms.

Lattice Diffusion

See *volume diffusion*.

Lattice Parameter

The length of any side of a unit cell of a given crystal structure. The term is also used for the fractional coordinates x , y , and z of lattice points when these are variables.

Lattice Pattern

A pattern of a filament winding with a fixed arrangement of voids.

Laue Method (for Crystal Analysis)

A method of x-ray diffraction using a beam of white radiation, a fixed single crystal specimen, and a flat photographic film usually normal to the incident beam. If the film is located on the same side of the specimen as the x-ray source, the method is known as the back reflection Laue method; if on the other side, as the transmission Laue method.

Launder

(1) A channel for transporting molten metal. (2) A box conduit conveying particles suspended in water.

Lava

Lava is molten rock material that reaches the Earth's surface through volcanic vents and fissures; also, the igneous rock formed by consolidation of such molten material. Relatively rapid cooling of the Earth's surface may transform fluid lava into a dense-textured volcanic rock composed of tiny crystals or glass or both.

The temperature of liquid lava ranges widely but generally does not exceed 1200°C. Basaltic lavas are usually hotter than rhyolitic ones. The viscosity of lava depends largely upon the temperature, composition, and gas content.

As lava cools, it becomes more viscous and the rate of flow decreases. Rapid cooling, as at the surface of a flow, promotes the formation of glass. Slower cooling as near the center of a flow, favors the growth of crystals.

During many volcanic eruptions, the lava is so rapidly ejected that it is blown to bits by the explosive force of expanding gases. The small masses rapidly congeal and settle to the Earth to form thick blankets of volcanic tuff and related pyroclastic rock. Lava flows and volcanic tuffs cover large areas of the Earth's surface and may form more or less alternating layers totaling many thousands of feet in thickness.

Lava is also a name given to ceramic material used for molding gas-burner tips, electrical insulating parts, nozzles, and handles. It may be calcined talc, steatite, or other material. It is molded from magnesium oxide, and it is hardened by heat treatment after shaping and cutting. It is baked at 1093°C. The compressive strength is from 138 to 207 MPa. It will resist moisture and has high dielectric

strength. Rods as small as 0.05 cm in diameter can be made. Alsimag is a trade name of lava that is produced from ground talc and sodium silicate, but *Alsimag 602* is phosphate-bonded steatite talc, used for thyratron tubes and as a substitute for mica in receiving tube spacers.

Laves' Phases

Intermediate phases formed from two metals in the ratio of one atom of one to two of the other, such as MgCu_2 , and where the two atoms differ in size by about 22.5% allowing them to form a close packed structure.

Law of Conservation of Matter

Matter is not created or destroyed during any chemical or physical process.

Lay

Direction of predominant surface pattern remaining after cutting, grinding, lapping, or other processing.

Lay (Composites)

The length of twist produced by stranding filaments, such as fibers, wires, or roving. The angle that such filaments make with the axis of the strand during a stranding operation. The length of twist of a filament is usually measured as the distance parallel to the axis of the strand between successive turns of the filament.

Layer

A stratum of weld metal or servicing material. The layer may consist of one or more weld beads laid side-by-side.

Layer Bearing

A bearing constructed in layers. See also *bimetal bearing* and *trimetal bearing*.

Layer Level Wound

See preferred term *level wound*.

Layer Wound

See preferred term *level wound*.

Layer-Lattice Material

Any material having a layerlike crystal structure, but particularly *solid lubricants* of this type.

LayUp

Reinforcing material that is placed in position in the mold. The process of placing the reinforcing material in position and the mold. The resin-impregnated reinforcement and a description of the component materials, geometry, and so forth, of a laminate.

LBBT

See *low blow brittle transition test*.

L/D Ratio

In bearing technology, the ratio of the axial length of a plain bearing to its diameter.

LD Process

See *Linz-Donawitz*.

L-Direction

The ribbon direction, that is, the direction of the continuous sheets of honeycomb.

Leaching

Extracting an element or compound from a solid alloy or mixture by preferential dissolution in a suitable liquid.

Lead Alkali Metals

Lead hardened with small amounts of alkali metals used chiefly as bearing metals. Alloys of this type are also called *tempered lead* and *alkali lead*. *Calcium-lead alloy* is made by electrolysis of the fused alkali salts, using a molten lead cathode and contains up to 1% calcium. The calcium forms a chemical compound, Pb_3Ca , with part of the lead, and the crystals of this compound are throughout the lead matrix. The Brinell hardness is 35, and the compressive strength is 172 MPa, being thus superior in strength to the high-tin bearing metals. But the metal is difficult to melt without oxidation and is easily corroded. The melting point is 370°C, and it retains its bearing strength at more elevated temperatures than the babbitts. *Calcium lead*, with about 0.04% calcium, is used as cable sheathing to replace antimonial lead, giving greater fatigue resistance. It is also used for grids in storage batteries and has a lower rate of self-discharge than antimonial lead. The small amount of lithium in *Bahnmetall* (original alkali lead) is intended to prevent the corrosion set up by the calcium. It also increases the compressive strength to about 207 MPa.

Lead and Alloys

A soft, heavy, bluish-gray metal (symbol Pb), lead is obtained chiefly from the mineral galena. It surface-oxidizes easily but is then very resistant to corrosion. It is soluble in nitric acid but not in sulfuric or hydrochloric, and is one of the most stable of the metals. Its crystal structure is face-centered cubic. It is very malleable, but it becomes hard and brittle on repeated melting because of the formation of oxides. The specific gravity of the cast metal was 11.34, and that of the rolled is 11.37. The melting point is 327°C, and boiling point is 1750°C. The tensile strength is low, that of the rolled metal being about 25 MPa, with the elongation of 30%. The coefficient of expansion is 0.0000183, and the thermal conductivity is 8.2% that of silver. The electric conductivity is only 7.8% that of copper. When used in storage batteries, the metal is largely returned as scrap after a period and is remelted and marketed as secondary lead, as is also that from pipes and cable coverings. Lead is highly toxic and, thus, poses a health hazard. Inhalation of dust and fumes should be avoided, and it should not be used in contact with food or drink products.

Not only is lead the most impervious of all common metals to x-rays and gamma radiation, it also resists attack by many corrosive chemicals,

most types of soil, and marine and industrial environments. Although it is one of the heaviest metals, only a few applications are based primarily on its high density. The main reasons for using lead often include low melting temperature, ease of casting and forming, good sound and vibration absorption, and ease of salvaging from scrap.

With its high internal damping characteristics, lead is one of the most efficient sound attenuators for industrial, commercial, and residential applications. Sheet lead, lead-loaded vinyls, lead composites, and lead-containing laminates are used to reduce machinery noise. Lead sheet with asbestos or rubber sandwich pads are commonly used in vibration control.

The natural lubricity and wear resistance of lead make the metal suitable, and alloys, for heavy-duty bearing applications such as railroad-car journal bearings and piston-engine crank bearings. Lead is also widely used as a constituent in solders. Most common solders are the lead-tin alloys; melting temperature can be as low as 183°C.

Forms**Sheet and Foil**

Because of its malleability, lead and its alloys are readily rolled to any desired thickness down to 0.01 mm. Sheets are usually fabricated by burning or soldering. Standard widths run to 2.4 m or more for sheet and sheets may be cut to any desired size. Blanks for impact extrusion, gaskets, washers, or other purposes may be stamped out. Tin-coated lead can be produced by rolling lead and tin together.

Extrusions

Lead is easily extruded in the form of pipe, rod, wire, or any desired cross section like window comes (H-shaped), rounds, hollow stars, rectangular duct. Commercially available extrusions range in size from 612 mm pipe down to solder wire 0.25 mm in diameter. Lead is extruded over paper, rubber, or plastic in making electrical cable and around steel bars. Common flux-cored solder is a lead extrusion; toothpaste tubes are impact extrusions.

Castings

One of the simplest metals to cast—lead is used in tiny die castings and massive cast counterweights. Type metal, renowned for its ability to reproduce minute detail, is a lead alloy. Lead grids for most batteries are die-cast. Casting temperature (usually about 316°C) is moderate. Arsenic, antimony, or tin are frequently alloyed to impart strength or special properties. Small die castings can have wall thicknesses as low as 1.3 mm and “as-cast” dimensions are reproducible to 0.03 mm.

Coatings

Protection of underlying iron and steel is the main objective in most lead coating. In the purely protective class one findsterne-plate for roofing, fireproof frames and doors, automotive parts, and containers for paint and oil. Lubricity imparted by the coating eases drawing and stamping operations and produces an excellent surface for soldering—hence, television chassis and automotive gas tanks are made of terne. Other hot-dip processes as well as electroplating and flame spraying are also used for outdoor hardware automotive mufflers, bearings, bushings, nuts, bolts, and for maintenance as well.

Laminations

Developed originally for x-ray protection, a large family of laminated lead materials now exists. In addition to their original niche, these are finding increasing use in sound isolation and noise control. Typical examples include lead-plywood, lead-gypsum board,

L

lead-cinder block, leaded plastic-fabric laminates, leaded plastic, and glass-fiber combinations.

Cladding

Metallic lead in thicknesses from 3.2 to 305 mm or more may be bonded to other metals. Thus, for example, lead and steel may be combined for corrosion resistance and strength or lead and copper for gamma shielding and heat transfer. In many instances, a product such as a tank or chemical reactor is completely or partially fabricated in steel and then clad with bonded lead as a unit.

Powder

Spheres, irregular grains, and flakes of lead from 4 μm diameter and above find use in special greases, as a constituent of bearings, brake, and clutch facings and in filling plastics and rubber and in paints and pile-joint compounds. Wire rope is usually treated with such a powder to lubricate it and to fill any nicks in the filter, thus renewing it with self-lubricating surfaces.

Shot

This form of lead is produced in abundance—about $30,360 \times 10^3$ kg go into shotgun ammunition each year. Ammunition sizes range from 1 to 11.3 mm; small shot is made for other uses. Easily handled, it is a preferred form when mass shielding is required inside an irregular enclosure. It is also used in making free-machining steels.

Wool

By passing molten lead through a fine sieve and allowing it to solidify in the air, a loose rope of fibers is produced. Under pressure, usually by being driven into a crevice with a caulking iron and hammer, the fibers weld into a homogeneous mass. This permits the forming of a solid metal seal where temperature or explosion hazards prohibit joining procedures requiring heat. Continuous lead fiber is also produced by being spun on textile machines.

Alloys

In its unalloyed form as 99.95% minimum, lead is soft and weak; it requires support for mechanical applications. This “chemical lead” is used primarily in corrosive chemical-handling applications such as tank linings.

“Hard lead”—lead alloyed with 1%–13% antimony—has sufficient tensile strength, fatigue resistance, and hardness for many mechanical applications. These alloys can be cast, rolled, or extruded and are especially suited for castings requiring good detail and moderate strength. Rolled antimonial alloys are harder and stronger than the cast alloys. Battery-plate lead contains 7%–12% antimony.

Calcium (0.03%–0.12%) forms another series of mechanically suitable alloys with lead. These alloys age-harden naturally at room temperature—usually for 30–60 days—after being cast or worked. Properties of wrought Pb–Ca alloys are somewhat directional, being greater in the longitudinal direction. Uses include cable sheathing and grids in storage batteries.

Tin, added to Pb–Ca alloys in amounts to about 1.5%, raises tensile strength and stress-rupture resistance but increases aging time to 180 days. Tin is often used to reduce the coefficient of friction for bearing applications. Higher-tin-bearing alloys are primarily used in solders, which normally contain from 40% to 60% tin.

Lead alloys may exhibit greatly improved mechanical or chemical properties as compared to pure lead. The major alloying additions to lead are antimony and tin. The solubilities of most other elements in lead are small, but even fractional weight percent

additions of some of these elements, notably copper and arsenic, can alter properties appreciably.

Cable-Sheathing Alloys

Lead is used as a sheath over the electrical components to protect power and telephone cable from moisture. Alloys containing 1% antimony are used for telephone cable, and lead-arsenical alloys, containing 0.15% arsenic, 0.1% tin, and 0.1% bismuth, for example, are used for power cable. Aluminum and plastic cable sheathing have replaced lead alloy sheathing in many applications.

Battery-Grid Alloys

Lead alloy grids are used in the lead-acid storage battery (the type used in automobiles) to support the active material composing the plates. Lead grid alloys contain 6%–12% antimony for strength, small amounts of tin to improve castability, and one or more other minor additions to retard dimensional change in service. No lead alloys capable of replacing the lead-antimony alloys in automobile batteries have been developed. An alloy containing 0.03% calcium for use in large stationary batteries has had success.

Chemical-Resistant Alloys

Lead alloys are used extensively in many applications requiring resistance to water, atmosphere, or chemical corrosion. They are noted for their resistance to attack by sulfuric acid. Alloys most commonly used contain 0.06% copper, or 1%–12% antimony, where greater strength is needed. The presence of antimony lowers corrosion resistance to some degree.

Type Metals

Type metals contain 2.5%–12% tin and 2.5%–25% antimony. Antimony increases hardness and reduces shrinkage during solidification. Tin improves fluidity and reproduction of detail. Both elements lower the melting temperature of the alloy. Common type metals melt at 238°C–246°C.

Bearing Metals

Lead bearing metals (babbitt metals) contain 10%–15% antimony, 5%–10% tin, and for some applications small amounts of arsenic or copper. Tin and antimony combine to form a compound that provides wear resistance. These alloys find frequent application in cast sleeve bearings and are used extensively in freight-car journal bearings. In some cast bearing bronzes, the lead content may exceed 25%.

Solders

A large number of lead-base solder compositions have been developed. Most contain large amounts of tin with selected minor additions to provide specific benefits, such as improved wetting characteristics.

Free-Machining Brasses, Brasses, Steels

Lead is added in amounts from 1% to 25% for brasses and bronzes to improve machining characteristics. Lead remains as discrete particles in these alloys. It is also added to some construction steel products to increase machinability. Only about 0.1% is needed, but the tonnage involved is so large that this forms an important use for lead.

Uses

Lead wool is lead in a shredded form used for caulking. Sheet lead is produced by cold-rolling and is used as a sound barrier in building construction.

Lead has a high capacity for the capture of neutrons and gamma rays and is used for radiation shielding in the form of sheet lead or as metal powder in ceramic mortars and blocks, paints, and in plastic composite structures. DS Lead is a dispersion-strengthened lead containing up to 1.5% lead monoxide evenly distributed through the structure. The oxide combines chemically with the lead, doubling the strength and stiffness of the metal, but increasing its brittleness. It is used for chemical piping and fittings. A neoprene-lead fabric is a neoprene fabric impregnated with lead powder. It has a radiation shielding capacity one third that of solid lead sheet. It comes in thicknesses of 0.08–0.64 cm, and its flexibility makes it suitable for protective clothing and curtains. Shielding cements for x-ray and nuclear installation shielding are metallic mortars containing a high percentage of lead powder with ceramic oxides as binders and other elements for selective shielding. They are mixed with water to form plasters or for casting into sections and blocks. The formulation varies with the intended use for capture, attenuation, or dissipation of neutrons, gamma rays, and other radiation. Shielding paints are blended in the same manner.

Battery-plate lead for the grid plates of storage batteries and silver alloy for positive-plate grids are additional applications. Lead-coated copper used for roofing and for acid-resistant tanks as well as frangible bullets, which shatter on striking a target surface and are used for aerial gunner practice, are two other uses.

Antimonial lead is an alloy containing up to 25% antimony with the balance lead, used for storage-battery plates, type metal, bullets, tank linings, pipes, cable coverings, bearing metals, roofing, collapsible tubes, toys, and small cast articles. The alloy is also known as hard lead.

One hard lead application has 10% antimony and 90% lead and melts at 252°C. Called cable lead, or sheathing lead, it is used to cover telephone and power cables to protect against moisture and mechanical injury. Terne-plate, as the coated steel is called, is widely used for automobile gasoline tanks and also has been used for roofing on buildings.

Lead Angle

In cutting tools, the helix angle of the flutes.

Lead Bronze

An alloy of copper with up to 30% lead use for high load bearings. Contrast with *leaded bronze* and *bearing bronzes*.

Lead Glass

Glass containing a substantial proportion of lead oxide (PbO).

Lead Oxide

Two types of lead oxide are used in ceramics: litharge, or lead monoxide, and red lead.

Litharge: Lead monoxide (PbO) has a specific gravity of 9.3–9.7; a melting point of 888°C. It is insoluble in water but soluble in alkalis, certain acids, and some chloride solutions.

Red Lead: Lead oxide (Pb₃O₄) has a specific gravity of 9.0–9.2; it decomposes between 500°C and 530°C. It is insoluble in water and is decomposed in some acids, leaving insoluble lead peroxide, PbO₂.

Lead oxide is used quite extensively in optical glass, electrical glass, and tableware. It increases the density and refractive index of glass. In addition, it can be cut more easily than other glasses and has superior brilliance, both of which make it good for cut glass.

Lead glasses may be formulated with a wide variety of electrical and acid-resistant characteristics; desirable properties, such as weather resistance, electrical resistivity, etc., will depend upon the total composition of the glass.

Lead has many advantages as a glaze ingredient. The superiority of lead glazes lies in their brilliance, luster, and smoothness, which are due to their lower fusion point and viscosity. Lead glazes are, in general, highly resistant to water solubility and chipping, and have few faults in texture and bond. They have high mobility, refractivity, and elasticity and are softer than leadless glazes.

All investigators agree that the use of fritted glazes, in which all of the lead is fritted, has important health advantages. In this way the raw lead oxide is converted into relatively harmless lead silicates, which are much less soluble in dilute acids or gastric juices. Lead silicates are more easily absorbed after entering the respiratory system, and can be eliminated with less lead absorption.

Lead oxide also is used in enamels. With an increase in lead and a corresponding decrease in potash, with flint constant, enamels become more fusible, have less tendency to craze, and become more refractive, but are less durable in acid fumes.

Lead Pigments

Chemical compounds of lead used in paints to give color. They are to be distinguished from the lead compounds such as lead oleate, used as driers for paints. *Lead flake* is useful in exterior primers, where it exhibits excellent durability and rust inhibition. But because of restrictions on the use of lead, lead flake and many other lead compounds are being phased out as pigments. *White lead* is the common name for *basic lead carbonate*, the oldest and most important lead paint pigment, also used in putty and in ceramics. It is a white, amorphous, poisonous powder. It is insoluble in water and decomposes on heating. The specific gravity is 6.7. It is made from metallic lead and is marketed dry, or mixed with linseed oil and turpentine in paste form. *Lead carbonate* is used as a pigment in the same way as the basic compound, but it discolors more easily. Basic lead sulfate, called *sublimed white lead*, makes a fine white pigment. Commercial sublimed white lead contains 75% lead sulfate, 20% lead oxide, and 5% zinc oxide. Commercial white lead may be mixed with lithopone, magnesium oxide, antimony oxide, witherite, or other materials.

The basic *silicate white lead* is made by fusing silica sand with litharge and hydrating by ball-milling with water. It has corrosion-inhibiting properties and is used in metal-protective paints for underwater service. It is also used in ceramics and as a stabilizer in vinyl plastics. *Basic lead silicate* is made from silica and litharge with sulfuric acid as a catalyst. The material has a core of silica with a surface coating of basic lead silicate, giving a pigment of lower weight per unit of volume but retaining the activity of the silicate white lead. *Chrome yellow*, or *Leipzig yellow*, is *lead chromate*, and it comes in yellow, poisonous crystals. Specific gravity is 6.123. It is insoluble in water and decomposes at 600°C. *Basic lead chromate*, is red and is used for anti-corrosive base coats for steel. *Red lead* is a bright orange pigment used exclusively for corrosion inhibition; because of its poor opacity it is combined with iron oxide. *Basic lead silicochromate* is another rust inhibitor. *American vermillion*, also called *Chinese scarlet* and *chrome red*, is basic lead chromate made from white lead.

L

Lead thiosulfate is a white insoluble powder used chiefly in matches. All of the lead compounds are poisonous when absorbed through skin or taken internally. *Lead sulfide* is used as a feeler in missiles as it is very sensitive to heat rays. Molybdate oranges are lead chromate, lead molybdate, and lead sulfate. DuPont Co's *Kroler* is a heat-resistant variety suitable for employment in plastics.

Litharge is the yellow *lead monoxide*, PbO, also called *massicot*. It is a yellow powder used as a pigment and in the manufacture of glass, and for the fluxing of earthenware. An important use is as a filler in rubber. With clustering, litharge is used as a plumber's cement. The specific gravity is 9.375. Litharge is produced by heating lead in a reverberatory furnace and then grinding the lumps. For storage-battery use the black oxide, or suboxide of lead, is now largely substituted. Lead dioxide, or lead peroxide, comes as a brown, crystalline powder and is used in making matches, dyes, and pyrotechnics, as a mordant, and as an oxidizing agent.

Lead Proof

See *die proof*.

Lead Zirconate Titanate

Lead zirconate titanate, $\text{Pb}(\text{Zr}_{0.4}\text{Ti}_{0.3})\text{O}_3$ to $\text{Pb}(\text{Zr}_{0.9}\text{Ti}_{0.1})\text{O}_3$, is also known as PZT ceramics. It is used mainly in the manufacture of piezoelectric ceramic elements.

The wide range of possible compositions provides a wide range of dielectric constant values, piezo-electric activity, and primary transition temperatures. These are normally greater than is possible with barium titanate. Small additions of niobium, strontium, barium, and antimony serve as modifiers.

To techniques for producing PZT powders are used today. Calcining (CMO) is the more common method of powder production, and the calcine is then formed and fired in its final shape.

PZT is the most widely used polycrystalline piezoelectric material. Its electrical output can measure pressure. It is used in hydrophones, which permit listening to sound transmitted through water.

One variation of the PZT ceramics is PLZT ceramics (lead-lanthanum zirconate titanate). They are a range of ferroelectric, optically active, transparent ceramics based on the $\text{PbZrO}_2\text{TiO}_2$ system. When hot pressed, the material can reach 99.8% theoretical density. For device applications of PLZT ceramics, the ratio that is important is $x:65:35$, where x is lanthanum (8%–10%) and 65:35 is the $\text{PbZrO}_3:\text{PbTiO}_3$ ratio. They have basically the same characteristics as PZT ceramics and are frequently finding use as filters, oscillators, and vibrators in many areas. They are also used for optical shutters.

Leaded Brass and Bronze

Any of the copper–zinc, copper–zinc–tin, and copper–tin alloys containing generally 1%–6% lead, sometimes more. The lead improves machinability, providing “free-machining” quality, but sacrifices ductility somewhat. Specific alloys are many, and they are available as wrought and cast alloys. Among the most common are the *leaded wrought brasses* (C31400–C38600), *leaded cast brasses* (C83300–C85800), *leaded phosphor bronzes* (C53200–C54800), and *leaded tin bronzes* (C92200–C92900).

Leaded Copper/Brass/Bronze, etc.

Metals to which lead has been added, primarily to make it free machining.

Leaded Steel

A free-machining steel containing about 0.25% lead. Lead does not alloy with iron, but when a stream of finely divided lead is shot at the stream of molten steel to the ingot mold, the lead is distributed in the steel in tiny particles. The lead eases machining without imparting to the steel the unfavorable characteristics given by sulfur or phosphorus. There is little weakening of the physical properties of the steel. The lead forms a layer of liquid lubricant at the chip–tool interface, thus reducing the stress required to overcome friction. Also, by slightly embrittling the steel, lead reduces the deformation stress and serves to initiate microcracks to produce small chips. *Ledloy*, of Inland Steel Co., contains 0.15%–0.30% lead in the regular SAE grades of steel.

Leak Testing

A nondestructive test for determining the escape or entry of liquids or gases from pressurized or into evacuated components of systems intended to hold these liquids. Leak testing systems, which employ a variety of gas detectors, are used for locating (detecting and pinpointing) leaks, determining the rate of leakage from one leak or from a system, or monitoring for leakage.

Leakage Field

The magnetic field that leaves or enters a magnetized part at a magnetic pole.

Leak-Before-Break

This term recognizes that some forms of failure are acceptable, others are not. In particular, a small leak is often acceptable; a major burst never is. Hence, a pressurized component known to be developing a crack might be considered acceptable to continue operation if it could be established that the crack would announce its development to an unacceptable stage by a slowly developing leak allowing ample time to shut down the plant before there was a possibility of a major explosion.

Lean Mixture

A gas/air mixture in which too much air is present, so that burning is difficult. The flame is usually noisy, frail, very light blue, short, and inefficient.

Least Count

The smallest value that can be read from an instrument having a graduated scale. Except on instruments provided with a *vernier*, the least count is that fraction of the smallest division that can be conveniently and reliably estimated; this fraction is ordinarily one-fifth or one-tenth, except where the graduations are very closely spaced. Also known as least reading.

Least Reading

See *least count*.

Leather

Leather is made from the hides or skins of animals, birds, reptiles, and fish. Two main steps are involved in this process. First, the hides

or skins are cured or dressed to prepare them for tanning. This curing process removes all the flesh, hair, and foreign matter. The hides are then tanned to produce durable, useful leather.

There are two general tanning methods—(1) bark or vegetable and (2) chrome tanning. In chrome tanning, salts of chromium are used to process the hides. Chrome-tanned leather cannot be tooled, but it can be dyed and embossed.

Vegetable tanning makes use of the tannic acid that is found in bark, leaves, and other vegetable products. Leather made by vegetable tanning is toolable and is, in general, the most suitable for leather craft.

Tanned leather, which is about the color of human skin, is smoother grained, but can be further finished by dyeing, glazing, buffing, graining, or embossing.

While the better leathers are usually left smooth, those having scratches, flaws, or other surface defects after tanning are generally embossed with a grain.

Leather can be purchased in many sizes and thicknesses. The thickness of leather is expressed either in ounces or fractions of an inch. When ounce is used it is really a measure of thickness, and not of weight. Leathers range from about 1 to 8 oz. The weight to use depends on the end-service requirements.

Types

Cowhide

This is a strong, tough, durable leather available in a very wide variety of grades, types, weights, finishes, and colors. Heavy vegetable-tanned cowhide back leather, ranging from 6 to 8 oz, is widely used for tooling, carving, and stamping. Heavy cowhide sides, sometimes called strap leather, are also suitable for tooling deep designs. Shoulder pieces are widely used for belts. Thinner cowhide, both vegetable and chrome tanned, is used in leather craft kits. Cowhide belly, lowest in cost and quality, can be used where appearance and durability are not important.

Calfskin

Calf has the finest grain of all tooling leathers and is therefore best for tooling. It ranges in weight from 1.5 to 3.5 oz; it is more expensive than cowhide. When moistened and tooled on the grain side, the designs will remain permanently. Calfskin is available in natural finish or in a variety of colors. Chrome-tan grades are less expensive than the tooling grades and are excellent for lining. (Vegetable-tanned calfskin is known as saddle leather.)

Steerhide

Steerhide has a crinkly surface, ranges in weight from about 2.5 to 4.5 oz, tools easily, and is not readily marred; it is available in many colors and in three-toned combination finish.

Sheepskin

Sheepskin is available in both tooling and nontooling grades. The largest nontooling use is for linings. Several types are available; suede, the best of lining leathers; skivers, thin and lightweight; glazed, with a fine, smooth glossy finish, and firm texture. All these are available in many different colors and are generally inexpensive.

The tooling grade is economical and tools without difficulty. Relatively deep tooling is also possible, but the leather should be dampened only very lightly. Sheepskin is often embossed or dyed to resemble calfskin.

Goatskin or "Morocco"

Although goat is naturally a fine-grained, smooth leather, it is most commonly seen with the pebbly or crinkly "morocco" grain produced by boarding. It is stronger and more attractive than sheepskin of the same finish. In the heavier weights, it is suitable for tooling line design and initials. Morocco leather is used extensively for book covers. Glazed goatskin has a high gloss, firm finish, and is excellent for lacing things.

Kidskin

Exceptionally thin, smooth, and strong, kidskin is characterized by tiny holes on the grain side. Excellent for lining, and available in various colors, it is used for lining, handbags, book covers, and wallets.

Pigskin

This leather has a fine grain and smooth surface with visible holes in groups of three. The finest grades are usually imported. Tooling of pigskin is very difficult and not recommended. It is an expensive leather and therefore its use is confined largely to small parts such as billfolds, card holders, and pocket secretaries.

Suede

Suede can be made from many kinds of leather, but most commonly from sheepskin. It has a soft velvet finish, it is nontooling and is suitable as a lining as well as for garments. Velvet Persian is a high-quality suede from skins of Persian sheep.

Alligator

Alligator is very expensive and is therefore restricted to small products. Besides genuine alligator, simulated alligator-grain leather is also available. It is usually made from calfskin or cowhide. It is attractive, strong, nontooling, available in many colors, and relatively inexpensive.

Snake and Lizard

Reptile skin is specialty leathers noted for the beauty of their markings. The skins are durable as well as beautiful. Because they are quite expensive, they are used only for very small items.

Ledeburite

The eutectic of the iron-carbon system, the constituents of which are *austenite* and *cementite*. The austenite decomposes into *ferrite* and *cementite* on cooling becomes A_{r_1} , the temperature at which transformation of austenite to ferrite, plus cementite is completed during cooling. See *steel*.

LEFM (Linear Elastic Fracture Mechanics)

See *fracture mechanics*.

Left-Hand Cutting Tool

A cutter all of whose flutes twist away in a counterclockwise direction when viewed from either end.

Leftward Welding

See *forward welding*.

L

Leg (Length)

In welding, the size of a fillet weld measured from the intersection of the two components to the toe at which the fused metal meets the parent metal.

Legging

The drawing of filaments or strings when adhesive-bonded substances are separated. Compare with *teeth*. See also *stringiness* and *webbing*.

Leg of Fillet Weld

(1) *Actual*: The distance from the root of the joint to the toe of the fillet weld. (2) *Nominal*: The length of the side of the largest right triangle that can be inscribed in the cross section of the weld. See also the terms *concave fillet weld* and *convex fillet weld*.

Lehigh (Slow) Bend Test

A test of the brittle fracture characteristics of steel usually after welding. It is basically a three point bend test using a notched specimen.

Lehigh (Weld) Cracking Test

A test of the susceptibility of steel to cracking during welding. The standard test piece is a plate 12 × 8 in., having a series of slots at 1 in. intervals along its two long sides and a central longitudinal slot to accept the weld. The longitudinal slot as of standard profile, but its length depends on the plate thickness. The depth of the side slots is selected to produce the required degree of restraint.

Leidenfrost Phenomenon

Slow cooling rates associated with a hot vapor blanket that surrounds a part being quenched in a liquid medium such as water. The gaseous water envelope acts as an insulator, thus slowing the cooling rate.

Lemon Bearing (Elliptical Bearing)

A two-lobed bearing.

Leno Weave

A locking-type weave in which two or more warp threads cross over each other and interlace with one or more filling threads. It is used primarily to prevent the shifting of fibers and open-weave fabrics.

Lens

A transparent optical element, so constructed that it serves to change the degree of convergence or divergence of the transmitted rays.

Lenticular

Shaped like a double convex lens.

Let-Go

An area in laminated glass over which an initial adhesion between interlayer and glass has been lost.

Letting Down

Tempering of steel particularly when carried out in a relatively crude matter with temperature estimated by color.

Level Winding

See *circumferential winding*.

Level Wound

Spooled or coiled weld filler metal that has been wound in distinct layers such that adjacent turns touch.

Leveler Lines

Lines on sheet or strip running transverse to the direction of *roller leveling*. These lines may be seen upon stoning or light sanding after leveling (but before drawing) and can usually be removed by moderate stretching.

Leveling

(1) Flattening of rolled sheet, strip, or plate by reducing or eliminating distortions. See also *stretcher leveling* and *roller leveling*. (2) Various processes for flattening sheet by light deformation either by uniform tensile loading or by passing the sheet through a series of staggered rollers.

Leveling Action

Action exhibited by a plating solution yielding a plated surface smoother than the basis metal.

Leveling Agents

Substances added to electrolytic plating solutions to minimize variations in plate thickness.

Lever Rule

A method that can be applied to any two-phase field of a binary *phase diagram* to determine the amounts of different phases present at a given temperature in a given alloy. A horizontal line, referred to as a tie line, represents the lever, and the alloy composition its fulcrum. The intersection of the tie line with the boundaries of the two-phase field fixes the compositions of the coexisting phases, and the amounts of the phases are proportional to the segments of the tie line between the alloy and the phase compositions.

Levigation

(1) Separation of fine powder from coarser material by forming a suspension of the fine material in a liquid. (2) A means of classifying a material as to particle size by the rate of settling from a suspension.

Levitation Melting

An *induction melting* process in which the metal being melted is suspended by the electromagnetic field and is not in contact with a container.

Life Assessment

Systems for estimating the remaining life of components such as power plant and other high-temperature, high duty plants. The term may be used of a simple calculation of creep life for comparison with the life experience. However, it more often refers to a comprehensive review of all information that can be obtained including original materials data and manufacturers certificates, site inspection and measurements, removal of samples for laboratory testing and examination, review of historical plant data, and reappraisal of design utilizing improved computer-based stress analysis techniques.

Life Fraction

The portion of life consumed by a particular set of circumstances. The concept is sometimes applied in damage mechanisms where the variables change. For example, in creep both the load and the temperature can vary, in fatigue to cyclic and steady loads may both vary. The life fraction approach involves calculating for each set of circumstances the life consumed as a fraction of the total life in those circumstances. Failure is assumed to occur when the fractions total unity.

Lift Beam Furnace

A continuously operating heat treating or sintering furnace. The term in general use by the U.S. furnace industry is *walking beam furnace*.

Lift Rod

Part of the press tooling used for the raising or lifting of one or more punches.

Liftout

The mechanism also known as *knockout*.

Ligament

In an engineering context, a load bearing part of a structure, for example, the metal remaining between a number of holes set across the line of loading.

Ligand

The molecule, ion, or group bound to the central atom in a *chelate* or a *coordination compound*.

Light

Radiant energy in a spectral range visible to the normal human eye (~380–780 nm, or 3800–7800 Å). See also *electromagnetic radiation*.

Light Drawn

An imprecise term, applied to drawn products such as wire and tubing, that indicates a lesser amount of cold reduction than for *hard drawn* products.

Light Filter

See *color filter*.

Light Fraction

The first liquid produced during the distillation of a crude oil.

Light Metal/Alloy

Any alloy based on the low density metals aluminum, magnesium, and, less common, lithium. Titanium and its alloys have a density intermediate between these and iron and copper and, depending on context, may be included in the category. Alloys of magnesium, beryllium, and lithium are sometimes termed ultra light. Examples of low-density metals, such as aluminum (~2.7 g/cm³), magnesium (~1.7 g/cm³), titanium (~4.4 g/cm³), beryllium (~1.8 g/cm³), or their alloys.

Light-Emitting Diodes (LEDs)

LEDs have been developed for numerous applications and systems for special lighting technology. For example, LEDs developed for experiments to activate light-sensitive, tumor-treating drugs. The light source, consisting of 144 of the tiny diodes, measures only 12.7 mm diameter—about the size of a small human finger. With its cooling system, the entire light source is the size of a medium suitcase. This type of therapy system involves injecting into the patient's bloodstream a drug, which attaches to the unwanted tissues and permeates into them, without affecting the surrounding tissues. A solid-state LED probe is placed near the affected tissue to illuminate the tumor and activate the drug. Once activated by the light, the drug destroys the tumor cells.

Light-Field Illumination

See *bright-field illumination*.

Lightly Coated Electrode

A filler-metal electrode used in arc welding, consisting of a metal wire with a light coating, usually of metal oxides and silicates, applied subsequent to the drawing operation primarily for stabilizing the arc. Contrast with *covered electrode*.

Lignin

A colorless to brown crystalline product recovered from paper-pulp sulfite liquor, and used in furfural plastics, as an extender of phenol in phenolic plastics, as a corrosion inhibitor, in adhesives and coatings, as a natural binder for compressed-wood products, and for the production of synthetic vanilla when it contains coniferin. It is also used as a fertilizer, providing humus and organic material and some sulfur to the soil. For this use, it may be mixed with phosphates. Lignin is coprecipitated with natural and synthetic rubbers to produce stronger and more lightweight products. When lignin is

incorporated into nitrile rubber by coprecipitation, the rubber has higher tensile and tear strengths and greater elongation than with an equal loading of carbon black.

Lignite

Also called *brown coal*. A variety of organic mineral of more recent age than coal, occurring in rocks of tertiary age, and intermediate in composition between wood and coal. It is widely distributed over Europe and found in many parts of the world. Freshly cut lignite often contains a large quantity of water, up to 40%, and is sometimes also high in ash. When dried, it breaks up into fine lumps and powder. Dry lignite contains 75% carbon, 10%–30% oxygen, and 5%–7% hydrogen. It kindles easily but burns with a low caloric power and a smoky flame. In retort gas production, lignite loses its gas in half the time required for gas removal from bituminous coal, with a temperature of 688°C, compared with 901°C for bituminous. The *pitch coal* is brownish black, breaks with a pitchlike fracture, and shows no woody structure. Lignite is briquetted by crushing and pressing with a binder under heat. Belgian lignite briquettes have a binder of 8% asphalt, with 2% flour to assist binding.

Lime

Lime, which is calcium oxide (CaO), has a specific gravity of 3.4, a melting point of 2572°C, boils at 2850°C, and is soluble. It is introduced into ceramic mixtures in several different forms. In the pottery bodies and glazes, it is bought as whiting (calcium carbonate) or dolomite (calcium carbonate and magnesium carbonate). In glass batches, it is introduced by limestone, burned lime (calcined limestone), and dolomite. In the enameling industry, it is used in the form of whiting.

Lime as CaO is not found in nature. Calcium carbonate, which is the chief source of lime, is found in the form of the minerals calcite and aragonite.

The chemical requirements of lime used in glass vary with the type of ware produced. The combined CaO and MgO should be at least 89% for bottle glass, 91% for sheet glass, 93% for blown glass, 96% for rolled glass, and 99% for optical glass. The iron oxide should be practically zero for optical glass, whereas in bottle glass as much as 0.5% is permissible, with nearly the same limits for blown or sheet glass. The silica or alumina may run as high as 15% for bottle glass, which should be vented much less for other grades.

Lime

A general term that includes the various chemical and physical forms of quicklime, hydrated lime, and hydraulic lime. It may be high-calcium, magnesium, or dolomitic. The chemical forms of CaO, calcium hydroxide (Ca(OH)₂), magnesium oxide (MgO), or magnesium hydroxide (Mg(OH)₂), alone or in combination may be produced either primarily or as a by-product of materials other than limestone, for example, Ca(OH)₂ formed by acetylene generation from calcium carbide (CaC₂) and water treatment sludges.

Lime Glass

A glass containing a substantial proportion of lime, usually associated with soda and silica. See also *glass*.

Limestone

A number of terms are in general use for the different varieties of limestone based on differences of origin, texture, composition, etc. *Marble* is a limestone that is more or less distinctly crystalline.

Chalk is a fine-grained aragonite limestone composed of finely divided calcium carbonate usually from marine shell sources.

It may be said, regardless of the impurities that are found in limestone, that lime is in all cases practically the only base found in a pure theoretical limestone. In glass, lime is one of the most important of the common batch ingredients.

Lime gives to glass, when added in proper quantities, stability or permanency, hardness, viscosity, and tenacity, and facilitate melting and refining. Line decreases the viscosity at high temperatures but increases the rate of setting in working range.

Magnesium lime or dolomitic lime is largely used because of its low iron content. Dolomitic lime seems to have a more powerful fluxing action and a glass using dolomitic lime is set to fine or plain up quicker than one using lime from another source.

Calcium carbonate is not used to the same extent in enamels as it is in glasses and glazes. This is probably because the average burning range of enamels is lower than that of either glasses or glazes, and calcium carbonate exerts strong fluxing action only at high temperatures.

Limestone is a sedimentary rock consisting chiefly of calcium carbonate or of the carbonates of calcium and magnesium. (1) Dolomitic limestone contains from 35% to 46% magnesium carbonate. (2) Magnesium limestone contains from 5% to 35% magnesium carbonate. (3) High-calcium limestone contains from 0% to 5% magnesium carbonate. Limestone is used extensively in glass formulations.

Limit of Proportionality

The stress below which a change in stress produces a linearly proportionate change in strain. See *tensile test*.

Limited Solid Solution

A crystalline miscibility series whose composition range does not extend all the way between the components of the system; that is, the system is not *isomorphous*.

Limited-Coordination Specification (or Standard)

A specification (or standard) that has not been fully coordinated and accepted by all interested parties. Limited-coordination specifications and standards are issued to cover the need for requirements unique to one particular department. This applies primarily to military agency documents.

Limiting Creep Stress

Originally, this referred to the stress below which no measurable creep occurs. Since this stress will depend on the sensitivity of the measuring equipment any remaining use of the term is usually specific to the application and the level of creep that is acceptable.

Limiting Current Density

The maximum current density that can be used to obtain a desired electrode reaction without undue interference such as from *polarization*.

Limiting Dome Height (LDH) Test

A mechanical test, usually performed unlubricated on sheet metal, that simulates the fracture conditions in a practical press-forming operation. The results are dependent on the sheet thickness.

Limiting Drawing Ratio (LDR)

See *deformation limit*.

Limiting Static Friction

The resistance to the force tangential to the interface that is just sufficient to initiate relative motion between two bodies under load. The term static friction, which properly describes a tangential resistance called into operation by a force less than this, should not be substituted for limiting static friction.

Limiting Stress Range

Same as *fatigue limit*.

Line Defect/Imperfection

Sometimes used as a synonym for *dislocation*.

Line Indices

The *Miller indices* of the set of planes producing a diffraction line.

Line Pair

In spectroscopy, an analytical line and the internal standard line with which it is compared. See also *internal standard line*.

Line Reaming

Simultaneous *reaming* of coaxial holes in various sections of a workpiece with a reamer having cutting faces or piloted surfaces with the desired alignment.

Lineage Structure

(1) Deviations from perfect alignment of parallel arms of a columnar dendrite as a result of interdendritic shrinkage during solidification from a liquid. This type of deviation may vary in orientation from a few minutes to as much as 2° of arc. (2) A type of substructure consisting of elongated subgrains. Individual areas have differences in lattice orientation that are detectable but not enough to constitute a grain boundary.

Linear (Tensile or Compressive) Strain

The change per unit length due to force in an original linear dimension. An increase in length is considered positive.

Linear Attenuation Coefficient

The fraction of an x-ray beam per unit thickness that a thin object will absorb or scatter (attenuate). A property proportional to the physical density and dependent on the atomic number of the material and the energy of the x-ray beam.

Linear Damage Law

A crude estimate of life fraction consumed is calculated. Failure occurs when the life fractions total unity.

Linear Dispersion

In spectroscopy, the derivative $dx/d\lambda$, where x is the distance along the spectrum and λ is the wavelength. Linear dispersion is usually expressed as mm/Å.

Linear Elastic Fracture Mechanics

A method of fracture analysis that can determine the stress (or load) required to induce fracture instability in a structure containing a cracklike flaw of known size and shape. See also *fracture mechanics* and *stress-intensity factor*.

Linear Expansion

The increase of a given dimension measured by the expansion of a specimen or component subject to a temperature gradient. See also *coefficient of thermal expansion*.

Linear Shrinkage

The shrinkage in one dimension of a powder compact during sintering. Contrast with *volume shrinkage*.

Linen

A general name for the yarns spun from the fiber of the variety of flax plant cultivated for its fiber, or for the cloth woven from the yarn. Linen yarns and fabrics have been made from the earliest times, and the ancient Egyptian linen fabrics were of exceeding fineness, containing 540 warp threads per inch, not equaled in Europe until the twentieth century. Ireland, Belgium, and France are the principal producers of linen. Linen yarns are used for the best grades of cordage, and linen fabrics are employed industrially wherever a fine, even, and strong cloth is required. *Linen fabrics* are sold under a wide variety of trade names. They are graded chiefly according to the fineness of the yarns and the class of weave and may contain some fine hemp fibers. *Lisle* was formally a fine, hard linen thread, made at Lille, France, but is now a fine, smooth yarn made of long-staple cotton spun tightly in a moist condition. *Tow yarns* are the coarsest linen yarns, use for making *crash*, a coarse, plain-woven fabric used for towels or covers. *Chintz* is a plain-woven linen fabric in brightly covered designs. It is also made as cotton chintz. The name is from the Hindu word meaning color. Damask is a jacquard reversible woven linen fabric for table linen. It is now also made in cotton, silk, or rayon.

Liner (Composite)

In a filament-wound pressure vessel, the continuous, usually flexible coating on the inside surface of the vessel, used to protect the laminate from chemical attack or to prevent leakage under stress.

Liner (Metals)

(1) The slab of coating metal that is placed on the core alloy and is subsequently rolled down to flat sheet as a composite. (2) In extrusion, a removable alloy steel cylindrical chamber, having an outside longitudinal taper firmly positioned in the container or main body of the press, into which the billet is placed for extrusion.

L

Liners

Thin strips of metal inserted between the dies and the units into which the dies are fastened.

Lining

Internal refractory layer of firebrick, clay, sand, or other material in a furnace or ladle.

Linishing

A method of finishing by grinding on a continuous abrasive belt.

Linoleum

A general name for floor-covering material consisting of a mixture of ground cork or wood flour, rosin or other gum, blown linseed oil, pigments, with sometimes a filler such as lithopone, on a fabric backing of burlap or canvas, rolled under pressure to give a hard, glossy surface. It is pigmented or dyed in plain colors, or printed with designs. The cork is usually in about 50-mesh particles. *Battleship linoleum*, a very heavy grade in plain colors or mosaics, is described in federal specifications as made with oxidized linseed oil, fossil or other resins or oxidized rosin, and an oleoresinous binder, mixed with ground cork, wood flour, and pigments, processed on a burlap back. Because of its resiliency, battleship linoleum is still valued for high-grade flooring and is coated with an adherent, wear-resistant lacquer based on cellulose ester and alkyd resins.

Linseed Oil

This oil is the most common of the drying oils, and it is widely used for paints, varnishes, linoleum, printing inks, and soaps. It is obtained by pressure from the seeds of the flax plant, which is cultivated for oil purposes. It is sometimes referred to as flaxseed, though this name properly belongs only to the seed of the flax plant for producing flax fiber. The varieties producing linen fiber do not yield much seed.

Linters

Short fibers adhere to the cottonseed if there ginning. Used in rayon manufacture as fillers for plastics and as a base for the manufacture of cellulosic plastics.

Linz-Donnawitz Process

The first (probably) commercial process to produce steel on a large scale by injecting oxygen into molten pig (impure) iron.

Lipophilic

Having an affinity for oil. See also *hydrophilic* and *hydrophobic*.

Lip-Pour Ladle

Ladle in which the molten metal is poured over a lip, much as water is poured out of a bucket. See the term *ladle*.

Liquation

(1) The separation of a low melting constituent of an alloy from the remaining constituents, usually apparent in alloys having a wide melting range. (2) Partial melting of an alloy, usually as a result of *coring* or other compositional heterogeneities.

Liquation (Cracking)

In its broadest sense this is a synonym for melting but usually implies transient localized melting of an alloy heated just to its solidus temperature. It normally occurs at the grain boundaries and may lead to other forms of damage such as oxide penetration down the boundaries or to cracking immediately or in subsequent service.

Liquation Temperature

The lowest temperature at which partial melting can occur in an alloy that exhibits the greatest possible degree of segregation.

Liquefied Petroleum (LP) Gas

Gases, such as propane and butane, which are usually stored as a liquid under pressure, but are released for use as a gas by a regulator.

Liquid Carburizing

Surface hardening of steel by immersion into a molten bath consisting of cyanides and other salts.

Liquid Chromatography

A separation method based on the distribution of sample compounds between a stationary phase and a liquid mobile phase. Used extensively in the characterization of organic, inorganic, pharmaceutical, and biochemical compounds. See also *chromatography*, *gas chromatography*, and *ion chromatography*.

Liquid Crystal Polymers

Liquid-crystal polymers (LCP) are a unique class of wholly aromatic polyester polymers that provide previously unavailable high-performance properties. Particularly outstanding is their heat-deflection temperature of 1.79 MPa at 238°C–318°C. Structure of the LCPs consists of densely packed fibrous polymer “chains” that provide self-reinforcement almost to the melting point.

Before the commercial introduction of LCP resins, LCPs could not be injection-molded. Today’s resin can be melt-processed on conventional equipment into thin-wall as well as heavy-wall components at fast speeds with excellent replication of mold details and efficient use of regrind.

Commercial melt-processable resins now available are Xydar formulations (biphenyl based) and Vectra resins (naphthalene based). Like most thermoplastics, molding these high-temperature resins requires heated tools and equipment capable of producing melt temperatures of 230°C–338°C for Vectra resins and 371°C–454°C for Xydar materials.

Properties

LCP resins are characterized by outstanding strength at extreme temperatures; excellent mechanical property retention after

exposure to weathering and radiation; good dielectric strength, arc resistance, and dimensional stability; low coefficient of thermal expansion; excellent flame retardance; and easy processability. Underwriters' Laboratories continuous-use rating for electrical properties is as high as 240°C and, for mechanical properties, 220°C. The high heat-deflection value of biphenyl-based resins permits molded parts to be exposed to intermittent temperatures as high as 315°C without affecting properties. Resistance to high-temperature flexural creep is excellent, as are fracture-toughness characteristics.

LCPs are exceptionally inert. They resist stress cracking in the presence of most chemicals at elevated temperatures, including aromatic or halogenated hydrocarbons, strong acids, bases, ketones, and other aggressive industrial substances. Hydrolytic stability in boiling water is excellent. Environments that determine the polymers are high-temperature steam, concentrated sulfuric acid, and boiling caustic materials.

The oxygen index of LCP resins ranges from 35% to 50%. When exposed to open flame, the material forms an intumescent char that prevents dripping and results in extremely low generation of smoke containing no toxic by-products.

Easy processability of the resins is attributed to its liquid-crystal molecular structure, which provides high melt flow and fast setup in molded parts. However, molded parts are highly anisotropic, and knit lines are much weaker than other areas. Properties are not affected by minor variations in processing conditions, and no post curing is required.

Liquid Crystals

These are nonisotropic materials—neither crystalline nor liquid—that are composed of long molecules parallel to each other in large clusters and that have properties intermediate between those of crystalline solids and liquids. It is estimated that 1 in every 200 organic compounds has the capability of being produced in the liquid crystal form.

There are three principal types of liquid crystals, based on the arrangement of the molecules. In the smectic type, the molecules are parallel with their ends in line, forming layers that are usually curved or distorted, but are still capable of movement over one another. In the nematic type, the molecules are essentially parallel, but there is no regular alignment of their ends. The cholesteric type is formed by optically active compounds that have the capability for molecular organizations of the nematic type.

Liquid crystals have some of the properties of liquids, such as fluidity, and some of the properties of crystals, such as optical anisotropy. A major use of liquid crystals is for digital displays, which consist of two sheets of glass separated by a sealed-in transparent liquid crystal material. The outer surface of the glass sheet is coated with a transparent conductive coating, with the viewing side coating etched into character-forming segments. A voltage applied between the two glass sheets disrupts the orderly arrangement of the molecules, thus darkening the liquid to form visible characters. Other typical applications of cholesteric liquid crystals are in skin thermography for tumor detection, in electronics for temperature mapping of circuits, and in nondestructive testing of laminates.

Liquid Disintegration

The process of producing powders by pouring molten metal on a rotating surface.

Liquid Honing

Producing a finely polished finish by directing an air-ejected chemical emulsion containing fine abrasives against the surface to be finished.

Liquid Impact Erosion

See *erosion (erosive wear)*.

Liquid Impingement Erosion

See *erosion (erosive wear)*.

Liquid Injection Molding (LIM)

A process that involves an integrated system for proportioning, mixing, and dispensing two-component liquid resin formulations and directly injecting the resultant mix into a mold, which is clamped under pressure. Generally used for the encapsulation of electrical and electronic devices. Also, variations on *reaction injection molding*, using mechanical mixing rather than a high-pressure impingement mixer. However, unlike mechanical mixing in other systems, the mixer here does not need to be flushed because a special feed system automatically dilutes the residue in the mixer with part of the polyol needed for the next shot, thereby keeping the ingredients from reacting.

Liquid Metal Attack/Embrittlement (ME)

Generally, any form of damage involving a liquid metal by corrosion, erosion, or dissolution. More specifically, especially when termed “embrittlement,” the term implies a mechanism in which liquid metal penetrates along grain boundaries or crystallographic planes of a higher melting temperature solid metal. Such attack is most likely when the metal is under stress, either applied, or residual. The thin planes of penetrating material may initiate cracks immediately or during subsequent service. For example, steel is usually brazed without problems but if, during brazing, it is subject to high levels of stress, either applied or residual, it is susceptible to deep brazing penetration at the grain boundaries.

Liquid Metal Infiltration

Process for immersion of metal fibers in a molten metal bath to achieve a metal–matrix composite; for example, graphite fibers in molten aluminum.

Liquid Nitriding

A method of surface hardening in which molten nitrogen-bearing, fused-salt baths containing both cyanides and cyanates are exposed to parts at some critical temperatures. A typical commercial bath for liquid nitriding is composed of a mixture of sodium and potassium salts. The sodium salts, which comprise 60%–70% (by weight) of the total mixture, consist of 96.5% NaCN, 2.5% Na₂CO₃, and 0.5% NaCNO. The potassium salts, 30%–40% (by weight) of the mixture, consists of 96% KCN, 0.6% K₂CO₃, 0.75% KCNO, and 0.5% KCl. The operating temperature of the salt bath is 565°C.

L

Liquid Nitrocarburizing

A nitrocarburizing process (where both carbon and nitrogen are absorbed into the surface) utilizing molten liquid salt baths below the lower critical temperature. Liquid nitro carburizing processes are used to improve wear resistance and fatigue properties of steels and cast irons.

Liquid Penetrant Inspection

A type of nondestructive inspection that locates discontinuities that are open to the surface of a metal by first allowing a penetrating dye or fluorescent liquid to infiltrate the discontinuity, removing the excess penetrant, and then applying a developing agent that causes the penetrant to seep back out of the discontinuity and register as an indication. Liquid penetrant inspection is suitable for both ferrous and nonferrous materials, but is limited to the detection of open surface discontinuities in nonporous solids.

Liquid Phase Diffusion Welding

See *diffusion welding*.

Liquid Phase Sintering

Sintering of a compact or loose powder aggregate under conditions where a liquid phase is present during part of the sintering cycle.

Liquid Resin

An organic, polymeric liquid that becomes a solid when converted to its final state for use.

Liquid Shim

Material used to position components in an assembly where dimensional alignment is critical. For example, epoxy adhesive is introduced into gaps after the assembly is placed in the desired configuration.

Liquid Shrinkage

The reduction in volume of liquid metal as it cools to the liquidus.

Liquid Spray Quench

Same as *spray quenching*.

Liquid–Liquid Chromatography (LLC)

Liquid chromatography with a stationary phase composed of a liquid dispersed onto an inert supporting material. Liquid–liquid chromatography has been used in the separation of phenols, aromatic alcohols, organometallic compounds, steroids, drugs, and food products. Also termed liquid-partition chromatography.

Liquid-Partition Chromatography (LPC)

See *liquid–liquid chromatography*.

Liquid–Solid Chromatography (LSC)

Liquid chromatography with silica or alumina as the stationary phase. See also *adsorption chromatography*.

Liquidus (Glass)

The maximum temperature at which equilibrium exists between the molten glass and its primary crystalline phase.

Liquidus (Metals)

(1) The lowest temperature at which a metal or an alloy is completely liquid. (2) In a *phase diagram*, the locus of points representing the temperatures at which the various compositions in the system begin to freeze on cooling or finish melting on heating. See also *solidus*. (3) The line on a phase diagram above which only the liquid phase is stable and below which solidification commences.

Liquor Finish

A smooth, bright finish characteristic of wet-drawn wire. Formerly produced by using liquor from fermented grain mash as a drawing lubricant.

Lithia

Lithia is the oxide of lithium, (LiO_2), usually added to ceramic batches by means of chemically prepared lithium compounds.

Lithia is a very powerful flux, especially when used in conjunction with potash and soda feldspars. It is a valuable component in glasses having a low thermal expansion where its use permits the total alkali content to be kept to a minimum. The low thermal expansion properties also are exploited in flameproof ceramic bodies and glass ceramics where the formation of beta spodumene is the basis for oven-to-tableware production. It also enables the production of certain glasses having high electrical resistance and desirable working properties. A relatively high content of lithia allows the production of glasses that transmit ultraviolet light.

Glasses containing lithia are much more fluid in the molten state than those containing proportional amounts of sodium or potassium, and a successful use of lithia in glassmaking lies in the fact that much smaller amounts are required to produce a glass of the necessary fluidity for working without sacrificing the desired physical and chemical properties. In addition, lithia is being utilized to increase furnace capacity, decrease melting temperatures, and increase production capacities.

Uses

Although lithium batteries boast the highest energy density of any rechargeable, cobalt in the cathode keeps cost high—a lithium battery for an electric vehicle cost about \$20,000. Computer modeling predicts a less expensive replacement material. Follow-on tests verify that a cathode made from a mixture of lithium aluminum oxide and lithium cobalt oxide could not only decrease battery cost by a significant margin, but also increase cell voltage.

Aluminum–lithium alloys are basically 2XXX and 7XXX aluminum alloys containing up to about 3% lithium. Because of the extremely light weight of lithium, they provide higher stiffness-to-density ratios than traditional structural aluminum alloys and, thus, have potential for aircraft applications. Because of the low

weight, lithium compounds give the highest content of hydrogen, oxygen, or chlorine. Lithium hydride, LiH , a white or gray powder, is used for the production of hydrogen for signal balloons and floats. Lithium aluminum hydride, or lithium alanate, LiAlH_4 , is used in the chemical industry for one-step reduction of esters without heat. Lithium metal is very sensitive to light, and is also used in light-sensitive cells.

Lithium is soluble in most commercial metals only to a slight extent; it is a powerful deoxidizer and desulfurizer of steel, but no lithium is left in the lithium-treated steel. In stainless steels it increases fluidity to produce dense castings. Cast iron treated with lithium has a fine grain structure and increased density with high impact value. Not more than 0.01% remains in the casting when treated with lithium–copper. In magnesium alloys the tensile strength is increased greatly by the addition of 0.05% lithium.

Lithium copper is a high conductivity, high density copper containing a minute quantity of residual lithium, 0.005%–0.008%, made by treating copper with a lithium–calcium–magnesium alloy.

Lithia has been widely used in the production of pottery glazes of high quality. The addition of 1% lithium carbonate in the frit or the fluoride or silicate in the mill to dinnerware, electrical porcelain, and sanitaryware glazes has been found to increase the resulting gloss to a marked degree.

Lithium

This lightest of all metals, symbol Li , has a specific gravity of 0.534. It is found in more than 40 minerals, but is obtained chiefly from lepidolite, spodumene, and salt brines.

Lithium melts at 186°C and boils at 1342°C . It is unstable chemically and burns in the air with a dazzling white flame when heated to just above its melting point. The melt is silvery white but tarnishes quickly in the air. The metal is kept submerged in kerosene. Lithium resembles sodium, barium, and potassium but has a wider reactive power than the other alkali metals. It combines easily with oxygen, nitrogen, and sulfur to form low melting-point compounds that pass off as gases, and is thus useful as a deoxidizer and degasifier of metals. In glass the small ionic radius of lithium permits a lithium ion coupled with an aluminum ion to displace two magnesium ions in the spinel structure. Lithium cobaltite, LiCoO_2 , and lithium zirconate, Li_2ZrO_3 , are also used in ceramics. Lithium carbonate, Li_2CO_3 , is a powerful fluxing agent for ceramics, and is used in low-melting ceramic enamels for coating aluminum. It is used in medicine to treat mental depression.

Uses

Lithium metal, 99.4% pure, is produced by the reduction of lithium chloride, LiCl . The salts of lithium burn with a crimson flame, and lithium chloride is used in pyrotechnics. It is also used for dehumidifying air for industrial drying and for air-conditioning, as it absorbs water rapidly. It is also employed in welding fluxes for aluminum and its storage batteries. The anode is lithium, the cathode is a lithium–tellurium alloy, and the electrolyte is a molten bath of lithium salts at 427°C . Lithium ribbon, for high-energy battery use, is 99.96% pure metal in continuous strip form, 0.05 cm thick. It comes on spools packed dry under argon. An anhydrous form of lithium hexafluoroarsenate powder is used as the anode in dry batteries.

Little-End Bearing

A bearing at the smaller (piston) end of a connecting rod in an engine. See also **big-end bearing**.

Live Center

A lathe or grinder center that holds, yet rotates with, the work. It is used in either the headstock or tail stock of a machine to prevent wear and reduce the driving torque.

Live Load

The variable portion of a load system, for example, the passengers in an elevator are the live load; the cabin is the fixed base or static load.

L Shell

The second shell of electrons surrounding the nucleus of an atom, having electrons with principal quantum number 2.

Load

(1) In the case of testing machines, a force applied to a test piece that is measured in units such as pound-force, newton, or kilogram-force. (2) In tribology, the force applied normal to the surface of one body by another contacting body or bodies. The term normal force is more precise and therefore preferred; however, the term normal load is also in use. If applied vertically, the load can be expressed in mass units, but it is preferable to use force units such as newtons (N). (3) The weight or force applied. It is not synonymous with stress—see *tensile test*.

Load Cell

A mechanism for measuring applied loads and, usually, embedding a signal for remote display or recording.

Load Controlled Loading

See *displacement controlled loading*.

Load Range (P)

In fatigue, the algebraic difference between the maximum and minimum loads in a fatigue cycle.

Load Ratio (R)

In fatigue, the algebraic ratio of the minimum to maximum load in a fatigue cycle, that is, $R = P_{\min}/P_{\max}$. Also known as *stress ratio*.

Load-Carrying Capacity (of a Lubricant)

(1) The maximum load that a sliding or rolling system can support without failure. (2) The maximum load or pressure that can be sustained by a lubricant (when used in a given system under specific conditions) without failure of moving bearings or sliding contact surfaces as evidenced by seizure or welding.

Load–Deflection Curve

A curve in which the increasing tension, compression, or flexural loads are plotted on the ordinate axis and the deflections caused by those loads are plotted on the abscissa axis.

L

Load–Extension Curve

The stress strain curve, as produced in the tensile test.

Loading

(1) In cutting, building up of a cutting tool back of the cutting edge by undesired adherence of material removed from the work. (2) In grinding, filling the pores of a grinding wheel with material from the work, usually resulting in a decrease in production and quality of finish. (3) In powder metallurgy, filling of the die cavity with powder.

Loading Sheet

In powder metallurgy, the part of a die assembly used as a container for a specific amount of powder to be fed into the die cavity. Sometimes it is part of the feed shoe.

Loading Weight

See preferred term *apparent density*.

Loam

A molding material consisting of sand, silt, and clay, used over brick work or other structural backup material for making massive castings, usually of iron or steel.

Lobed Bearing

A journal bearing which two or more lobes, around its periphery produced by machining or by elastic distortion to increase stability or to provide adjustable clearance.

Local Action

Corrosion due to the action of “local cells,” that is, galvanic cells resulting from inhomogeneities between adjacent areas on a metal surface exposed to *electrolyte*. The electrolytic corrosion occurring at small, localized variations in composition or hardness.

Local Cell

A *galvanic cell* resulting from inhomogeneities between areas on a metal surface in an *electrolyte*. The inhomogeneities may be of physical or chemical nature in either the metal or its environment.

Local Current Density

Current density at a point or on a small area.

Local Preheating

Preheating a specific portion of a structure.

Local Stress Relief Heat Treatment

Stress relief heat treatment of a specific portion of a structure.

Localized Corrosion

Corrosion at discrete sites, for example, *crevice corrosion*, *pitting*, and *stress-corrosion cracking*.

Localized Precipitation

Precipitation from a supersaturated solid solution similar to *continuous precipitation*, except that the precipitate particles form at preferred locations, such as along slip planes, grain boundaries, or incoherent twin boundaries.

Locating Boss

A *boss*-shaped feature on a casting to help locate the casting to an assembly or to locate the casting during secondary tooling operations.

Locating Ring

In injection molding machine, a ring that serves to align the nozzle of an injection cylinder with the entrance of the sprue bushing and the mold to the machine platen.

Locational Fit

A clearance or interference *fit* intended for locating mating parts.

Lock

In forging, a condition in which the flash line is not entirely in one plane. Where two or more plane changes occur it is called compound lock. Where a lock is placed in the die to compensate for die shift caused by a steep lock, it is called a counterlock.

Lock (ed) Fit

A severe interference fit not capable of being parted.

Lock Nut

A second solid nut tightened hard against the first nut on a threaded component to prevent loosening in service as a result of vibration or other inadvertent loads. Apart from the obvious risks associated with a nut falling off, even small reductions in pre-load increases the risk of fatigue failure. Where the nuts differ in thickness the thicker should be fitted last as it carries the full tightening torque and pre-load. It is incorrect but not uncommon for the thin nut to be fitted second. Alternative names are *jam nut* and *thin nut*. Another form of lock nut is of a thin hard sheet with edges raised to receive the wrench. These are not tightened to full pre-load torque and are fitted second. Also see *self locking nut*.

Locked Dies

Dies with mating faces that lie in more than one plane.

Logarithmic Decrement (Log Decrement)

The natural logarithm of the ratio of successive amplitudes of vibration of a member in free oscillation. It is equal to one/half the specific damping capacity.

Long Period

A morphological parameter for plastics obtained from small-angle x-ray scattering. It is usually equated to the sum of the *lamellar thickness* and the amorphous thickness.

Long Range Order

An ordered structure extending over a large proportion of a crystal.

Long Ton

The Imperial ton of 2240 lb as opposed to the U.S. "Short Ton" of 2000 lb.

Long Transverse

See *transverse*.

Long-Chain Branching

A form of molecular branching found in addition polymers as a result of an internal transfer reaction. It primarily influences the melt flow properties.

Longitudinal

In a metallurgical context, it is the line along which a material is principally extended during a working operation.

Longitudinal Direction

That direction parallel to the direction of maximum elongation in a work material. See also *normal direction* and *transverse direction*.

Longitudinal Field

A magnetic field that extends within a magnetized part from one or more poles to one or more other poles and that is completed through a path external to the part.

Longitudinal Resistance Seam Welding

The making of a resistance seam welding and a direction essentially parallel to the throat depth of a resistance welding machine.

Longitudinal Sequence

The order in which the increments of a continuous weld are deposited with respect to its length. See also *backstep sequence* and *block sequence*.

Long-Line Current

Current that flows through the earth from an anodic to a cathodic area of a continuous metallic structure. Usually used only where the areas are separated by considerable distance and where the current results from concentration-cell action.

Longos

Low-angle helical or longitudinal filament windings.

Long-Term Etching

Etching times of a few minutes to hours.

Loop Classifier

A cyclone-type classifier sometimes connected with a conical ball mill in an airtight system.

Loop Tenacity

The tenacity or strength value obtained by pulling two loops, such as two links in a chain, against each other to demonstrate the susceptibility of a fibrous material to cutting or crushing; loop strength.

Looping Mill

An arrangement of hot rolling stands such that a hot bar, while being discharged from one stand, is fed into a second stand in the opposite direction. See *rolling mill*.

Loose Metal

Refers to an area in a formed panel that is not stiff enough to hold its shape, may be confused with *oil canning*.

Loose Powder

Uncompacted powder.

Loose Powder Sintering

Sintering of uncompacted powder using no external pressure.

Loss Factor

The product of the dissipation factor and the dielectric constant of a dielectric material. See also *tan delta*.

Loss Modulus

A quantitative measure of energy dissipation in polymers, defined as the ratio of stress 90° out of phase with oscillating strain to the magnitude of strain. The loss modulus may be measured in tension or flexure, compression, or shear. See also *complex modulus*.

Loss On Ignition (LOI)

(1) The fractional or percentage weight loss of a material on heating in air from an initial defined state (usually, dried) to a specified temperature, such as 1000°C (1830°F), and holding therefore a specified period, such as 1 h. Fixed procedures are designed, usually, such that LOI represents the loss of combined H₂O, CO₂, certain other volatile inorganics, and combustible organic matter. (2) Weight loss, usually expressed as a percent of the total, after burning off an organic sizing from glass fibers, or an organic resin from a glass fiber laminate.

L

Lost Foam Casting

An *expendable pattern* process in which an expandable polystyrene pattern surrounded by the unbonded sand, is vaporized during pouring of the molten metal. Also referred to as evaporative pattern casting, evaporative foam casting, the lost pattern process, the cavity-less expanded polystyrene casting process, expanded polystyrene molding, or the full mold process.

Lost Wax Process

An *investment casting* process in which a wax pattern is used.

Lot

(1) A specific amount of material produced at one time using one process and constant conditions of manufacture, and offered for sale as a unit quantity. (2) A quantity of material that is thought to be uniform in one or more stated properties such as isotopic, chemical, or physical characteristics. (3) A quantity of bulk material of similar composition whose properties are under study. (4) A definite quantity of a product or material accumulated under conditions that are considered uniform for *sampling* purposes. Compare with *batch*.

Lot Sample

See *gross sample*.

Low Blow Brittle Transition Test

Similar to the Charpy Impact test except that the standard notched test pieces are pre-cracked by an initial impact at a temperature above the transition temperature. A series of test pieces is then tested, as normal, over a range of temperatures to produce the usual graph of energy absorbed against temperature. The technique is expected to produce a graph with a distinct inflection point at the temperature which, it is claimed, is the lowest safe service temperature for the batch of material. This temperature is termed the Low Blow Brittle Transition Temperature (*LBTT*).

Low Frequency Resistance Welding Cycle

One positive and one negative pulse of current within the same weld or heat time at a frequency lower than the power supply frequency from which it is obtained.

Low Hysteresis Steel

See *transformer steel*.

Low Melting Temperature Alloys

Various alloys with a low melting point, the criterion usually being 232°C, the melting point of tin. The constituents are usually two or more from tin, lead, bismuth, cadmium, gallium, thallium, indium and zinc. Compositions are often eutectics to ensure a sharp melting point. Some of the alloys are molten at ambient temperature. Applications include fusible plugs, sprinkler activators, tube bending fillers, and Jaeger die applications. Also termed *Fusible Alloys*. See *Wood's Metal* as an example.

Low-Alloy Carbon Steels

Also known by other terms, including alloy constructional steels, these are generally limited to a maximum alloy content of 5%. One or more of the following elements may be present: manganese, nickel, chromium, molybdenum, vanadium, and silicon. Of these, nickel, chromium, and molybdenum are the most common. The steels are designated by a numerical code prefixed by AISI (American Iron and Steel Institute) or SAE (formerly Society of Automotive Engineers). The last two digits show the nominal carbon content. The first two digits identify the major alloying element(s) or group. For example, 2317 is a nickel-alloy steel with a nominal carbon content of 0.17%.

Whereas surface hardness attainable by quenching is largely a function of carbon content, the depth of hardness depends in addition on alloy content. Therefore, a principal feature of low-alloy steels is their enhanced hardenability compared to plain carbon steels. Like plain carbon steels, however, the mechanical properties of low-alloy steels are closely related to carbon content. In heat-treated, low-alloy steels, the alloying elements contribute to the mechanical properties through a secondary hardening process that involves the formation of finely divided alloy carbides. Therefore, for a given carbon content, tensile strengths of low-alloy steels can often be double those of comparable plain carbon steels.

Low-alloy steels may be surface-hardening (carburizing) or through-hardening grades. The former are comparable in carbon content to low-carbon steels. Grades such as 4023, 4118, and 5015 are used for parts requiring better core properties than are obtainable with the surface-hardening grades of plain carbon steel. The higher-alloy grades, such as 3120, 4320, 4620, 5120, and 8620, are used for still better strength and core toughness.

Most through-hardening grades are medium in carbon content and are quenched and tempered to specific strength and hardness levels. These steels also can be produced to meet specific hardenability limits as determined by end quenched tests. Identified as H steels, they afford steel producers more latitude in chemical composition limits. The boron steels, which contain very small amounts of boron, are also H steels. They are identified by the letter B after the first two digits.

A few low-alloy steels are available with high carbon content. These are mainly spring-steel grades 9260, 6150, 5160, 4160, and 8655, and bearing steels 52100 and 51100. The principal advantages of low-alloy spring steels are their high degree of hardenability and toughness. The bearing steels, because of their combination of high hardness, wear resistance, and strength, are used for a number of other parts, in addition to bearings.

Low-Alloy, High-Strength Steels

High-strength, low-alloy (HSLA) steels are low- to medium-carbon (0.10%–0.30%)/manganese (0.6%–1.70%) steels containing small amounts of alloying elements, such as aluminum, boron, chromium, columbium, copper, molybdenum, nickel, nitrogen, phosphorus, rare earth metals, titanium, vanadium, and zirconium. Because of the small amount of some of these elements, these steels have been referred to as microalloyed steels. The chemical compositions and minimum mechanical properties of the steels are commonly designated by minimum tensile yield strength, which ranges from about 241 MPa to more than 552 MPa. They are available in most mill forms with hot-rolled sheet and plate probably the most common, and they are typically used in the as-supplied condition. Thus, they provide high-strength without heat treatment by users, and that is the principal reason for their use, which includes structural applications in cars and cargo vessels, rail cars, and agricultural, earthmoving, and materials handling equipment as well as office buildings and highway bridges.

HSLA steels are tougher than plain carbon steels; they are not quite as formable, although sheet grades having yield strengths of 345 MPa can be formed at room temperature to 1T (one times thickness) to 2T bends, depending on thickness. The most formable are those produced with inclusion-shape control. That is, with the use of special alloying ingredients, such as rare earth metals, titanium, and zirconium, and controlled-cooling practice, resulting inclusions are small dispersed globules rather than stringer-like in shape. They are also relatively welded by all common methods, and can be brazed and soldered. Most of the steels are two to eight times more resistant to atmospheric corrosion than plain carbon steels, and those commonly called weathering steels naturally acquire a deep purple-brown corrosion-inhibiting surface that precludes painting for corrosion protection. The color is considered attractive, especially in rural areas, and, thus, the steels have found considerable use for exposed building members and highway applications. Dual-phase HSLA steel has a deformable martensite phase in the ferrite matrix and exhibits a high rate of strain hardening during cold working. In the as-rolled condition in which it is supplied, it has a tensile yield strength of about 345 MPa and, thus, the ductility (about 30% tensile elongation) and formability of conventional HSLA steels of this strength level. But strains of 2%–3% during forming operations will increase yield strength in the strained regions to 552 MPa or greater. Thus, the steel provides a formability of medium-strength HSLA steels and the opportunity to achieve strength levels in selected regions equivalent to those of stronger, but less formable, as-supplied grades.

As contrasted to the HSLA steels, quenched-and-tempered steels are usually treated at the steel mill to develop optimum properties. Generally low in carbon, with an upper limit of 0.2%, they have minimum yield strengths from 551 to 861 MPa. Some two dozen types of proprietary steels of this type are produced. Many are available as three or four different strengths or hardness levels. In addition, there are several special abrasion-resistant grades. Mechanical properties are significantly influenced by section size. Hardenability is chiefly controlled by the alloying elements. Roughly, an increase in alloy content counteracts the decline of strength and toughness as section size increases. Thus, specifications for the steels take section size into account. In general, the higher-strength grades have endurance limits of about 60% of their tensile strength. Although their toughness is acceptable, they do not have the ductility of HSLA steels. Their atmospheric-corrosion resistance in general is comparable, and in some grades, it is better. Most quenched-and-tempered steels are readily welded by conventional methods.

Applications

High-strength steels can be used advantageously in any structural application where their greater strength can be utilized either to decrease the weight or increase the durability of the structure.

Although high-strength steels find application in all recognized market classifications, the largest single field of application has been in the manufacture of construction machinery and transportation equipment. One of the leading grades of high-strength steel has been used in the construction of railroad freight cars and railroad passenger cars.

In bridges, designers are increasingly recognizing the importance of reducing deadweight by using high-strength steels, particularly for bridges involving long spans in which a reduction of weight at the center permits additional savings in the weight of supporting members. High-strength steels also lend themselves to economical lower construction where the properties permit the use of section smaller than would be required in structural carbon steel. This advantage

is important to tall television towers where dynamic loading due to wind resistance is lessened by use of smaller sections, and in transmission towers where lighter weight is a substantial advantage in reducing freight and handling costs.

Another use of high-strength steels has been for columns in high-rise buildings. Judicious use of high-strength steels in place of, and in combination with, structural carbon steel can result in substantial cost savings and an increase in usable floor area. High-strength steels are also being used to advantage in framing members of industrial and farm buildings.

The weight of containers for liquefied petroleum gas has been reduced appreciably by the use of high-strength steel, making them easier and less costly to handle and ship. Almost all such containers are now made of high-strength steel.

Other applications of high-strength steels include the inner bottoms, floors, tanks, and hatch covers of ore boats; hulls and other structural members of small tankers, barges, tugs, launches, and riverboats; coal bunkers; street lighting poles; portable oil-drilling rigs; jet-blast fences; cable reels; automobile bumpers; pole-line hardware; air-conditioning equipment; stokers; agricultural-machinery parts; earthmoving equipment; military and domestic shipping containers; and air-preheater units.

Low-Carbon Ferritic Steels

Low-carbon ferritic steels, which were developed by Inco, Ltd., are low-alloy steels containing nickel, copper, and columbium. They are precipitation-hardened and have yield strengths from 482 to 689 MPa and sections up to 1.9 cm. They possess excellent welding and cold-forming characteristics. A major use of these steels has been for vehicle frame members. Atmospheric corrosion resistance is roughly three or four times that of carbon steels.

Low-Cycle Fatigue

Fatigue that occurs at relatively small numbers of cycles ($<10^4$ cycles). Low-cycle fatigue may be accompanied by some plastic, or permanent, deformation. Compare with *high-cycle fatigue*.

Low-Energy Electron Diffraction

A technique for studying the atomic structure of single-crystal surfaces, in which electrons of uniform energy in the approximate range of 5–500 eV are scattered from a surface. Those scattered electrons that have lost no energy are selected and accelerated to a fluorescent screen where the diffraction pattern from the surface is observed.

Lower Bainite

Bainite formed at relatively low temperature as a result of cooling at a rate not quite sufficient to form martensite. See *steel* and *isothermal transformation diagram*.

Lower Ram

The part of a pneumatic or hydraulic press that is moving in a lower cylinder and transmits pressure to the lower punch. See the term *hydraulic press*.

Lower Shelf

See *brittle fracture*.

L

Lower Yield

See *tensile test*.

Low-Expansion Alloys

These are alloys, mainly of iron and nickel, having low coefficients of thermal expansion, usually within a specific temperature range. Uses include precision-instrument parts requiring dimensional stability at various temperatures and glass-to-metal ceiling applications, in which the thermal expansivity of the metal must closely match that of the glass. The best-known alloy Invar, also known as Nilvar, an iron–36% nickel composition also containing (as impurities) minute amounts of carbon, manganese, and silicon. It has a lowest coefficient of thermal expansion of all metals in the -273°C to 177°C range. In the annealed condition, the alloy has the coefficient of thermal expansion ranging from about $1.44\text{ m/m/K} \times 10^{-6}$ at -17.8°C to 25°C . At 149°C , the value is still only $1.8\text{ m/m/K} \times 10^{-6}$. Expansivity is affected by heat treatment and cold work. Quenching from about 830°C , for example, reduces the coefficient of thermal expansion below that of annealed material, as does cold forming. A combination of quenching and cold work can even result in zero or negative coefficients. Invar has a thermal conductivity of 11 W/m K from room temperature to 100°C and is quite soft, with a hardness of about Brinell 160. Tensile properties are about 517 MPa ultimate strength, 345 MPa yield strength, and 35%–40% elongation. The alloy is ferromagnetic at room temperature but becomes paramagnetic with increasing temperature. Because the thermal expansivity of the alloy is rather constant within a specific temperature range, Invar is also known as a controlled-expansion alloy.

There are many other such alloys, each suited for specific coefficients of thermal expansion within certain temperature ranges. They include iron with 39% nickel, or Fe–39Ni, Fe–42Ni (Dumet and Alloy 42), Fe–48Ni (Platinite), Fe–48.5Ni, Fe–50.5Ni, Fe–42Ni–6Cr, Fe–45Ni–6Cr, Fe–36Ni–12Cr (Elinvar), Fe–22Ni–3Cr, and Fe–42Ni–5.5Cr–2.5Ti–0.40Al (NiSpan C and Elinvar Extra). Besides its low coefficient of thermal expansion, Elinvar is noted for its constant modulus of elasticity over a wide temperature range.

Cobalt in iron–nickel alloys increases the coefficient of thermal expansion at room temperature but enhances thermal stability over a wider temperature range. Kovar and Fernico, Fe–28Ni–18Co alloys, and Fernichrome (Fe–30Ni–25Co–8Cr) are used for applications requiring vacuum sealing to glass. A Co54–Fe37–Cr9 alloy is noted for its near-zero and sometimes negative coefficient of thermal expansion in the 0°C – 100°C range. Elgiloy (40Co–20Cr–15.5Ni–15.3Fe–7Mo–2Mn–0.15C–0.04Be), originally a watch-spring alloy, has found many more spring applications. Besides dimensional stability, the alloy is noted for its good fatigue strength, corrosion and heat resistance, and nonmagnetic characteristics. Incoloy 903 (42Fe–38Ni–15Co–3Cb–1.4Ti–0.7Al), which is also heat-treatable, is noted for a new constant coefficient of thermal expansion, about $7.2\text{ m/m/K} \times 10^{-6}$ from 100°C to 427°C and a near-constant modulus of elasticity from -196°C to 649°C .

Other low-expansion or controlled-expansion alloys that have been developed include Nivar, which contains 54% cobalt; the Swiss alloys Nivarox (Fe–37Ni–8Cr with small amounts of manganese, beryllium, silicon, and carbon) and Contracid (60Ni–15Cr–15Fe–7Mo–2Mn and small amounts of beryllium and silicon); the French iron–nickel alloys Dilvar and Adr; Super-Invar from Japan, a 5% cobalt; iron–nickel alloy; Sylvania 4 (Fe–42Ni–5.7Cr with small amounts of manganese, silicon, carbon, and aluminum) and the similar Sealmet HC-4; Niron 52 (52Ni–48Fe); Rodar (Fe–29Ni–17Co–0.3Mn); and Nicromet (54Fe–46Ni).

Low-Hydrogen Electrode

A covered arc welding electrode that provides an atmosphere around the arc and molten weld metal that is low in hydrogen.

Low-Pressure Laminates

In general, composite laminate's molded and cured in the range of pressures from 2760 kPa (400 psi) down to and including pressure obtained by the mere contact of the plies.

Low-Pressure Molding

The distribution of relatively uniform low-pressure (1400 kPa, or 200 psi, or less) over a resin-bearing fibrous assembly of cellulose, glass, asbestos, or other material, with or without application of heat from an external source, to form a structure possessing specific physical properties.

Low-Profile Resins

Special polyester resin systems for reinforced plastics that are combinations of thermoset and thermoplastic resins. Although the terms of low-profile and low-shrink are sometimes used interchangeably, there is a difference. Low shrink resins contain up to 30 wt.% thermoplastic polymer, while low-profile resins contain from 30 to 50 wt.%. Low shrink offers minimum surface waviness in the molded part (as low as $25\text{ }\mu\text{m}/25\text{ mm}$, or 1 mil/in., mold shrinkage); low profile offers no surface waviness (from 12.7 to $0\text{ }\mu\text{m}/25\text{ mm}$, or 0.5 to 0 mils/in., mold shrinkage).

Low-Residual-Phosphorus Copper

Deoxidized copper with residual phosphorus present in amounts (usually 0.004%–0.012%) generally too small to decrease appreciably the electrical conductivity of the copper.

Low-Shaft Furnace

A short shaft-type blast furnace used to produce pig iron and Ferro alloys from low-grade ores, using low-grade fuel. The air blast is often enriched with oxygen. Also used for making a variety of other products such as alumina, cementmaking slags, and ammonia synthesis gas.

Low-Shrink Resins

See *low-profile resins*.

Low-Stress Abrasion

A form of abrasion in which relatively low contact pressures on the abrading particles or protuberances cause only fine scratches and microscopic cutting chips to be produced. See also *high-stress abrasion*.

LPG

Liquid Petroleum Gas.

L-Radiation

Characteristic x-rays produced by an atom or ion when a vacancy in the L shell is filled by an electron from another shell.

L-Series

The set of characteristic x-ray wavelengths making up L-radiation for the various elements.

Lubricant

Materials imposed at the interface between surfaces in relative motion. Their primary function is to keep the surfaces apart and hence avoid surface damage and seizure. Clearly they should minimize friction and they may also act as coolants. (1) Any substance interposed between two surfaces in relative motion for the purpose of reducing the friction or wear between them. This definition implies intentional addition of a substance to an interface; however, species such as oxides and tarnishes on certain metals can also act as lubricants even though they were not added to the system intentionally. (2) A material applied to dies, molds, plungers, or workpieces that promotes the flow of metal, reduces friction and wear, and aids in the release of the finished part. (3) Lubricants may be solids including graphite and PTFE, semi solids including grease and animal fats, liquid including oil and water (in appropriate cases), glass (*see Uging Process*) or gas including air.

Lubricants

Lubricants are substances that facilitate the flow of nonplastic, or poorly plastic, materials in the formation of dense compacts under pressure. Lubricants, which may be liquids or solids, either organic or inorganic, are particularly useful in dry pressing. Pieces formed under high pressure are apt to stick to the die, and even more so if the die is of intricate design.

It has been shown that proper lubrication of the die and of the powders to be pressed does much to equalize pressure in the piece. Lubricants reduce the friction between particles, and particles and die surfaces. This results in denser compacts, possible use of lower forming pressures, and easier ejection.

According to some investigators, the major cause of pressure variation is due to die surface friction. It has been shown by them that a stearic acid lubricant applied to the die walls completely eliminated pressure variations. Since it is impractical, in many cases, to lubricate the die after each operation, lubricants must be added to the powders.

Lubricants can be added directly to the powder batch, or, in other cases, special techniques must be used, such as hot mixing to disperse low-melting-point solids. The total amount of lubricants, with other special additives, ranges from ~0.1% to ~10% of batch weight. The lubricants themselves usually are used in less than 5% amounts. Actual concentrations depend on the basic nature of the body and the complexity of the shape.

Some lubricants also serve as binders and plasticizers. These are beneficial secondary functions and might serve as a basis for selecting one lubricant over another. Other factors to be considered are the compatibility of the lubricant with the body and the manufacturing processes, possible discoloration in the fired state, undesirable residues, and the effect on glaze application.

Types

Descriptions of typical lubricants that have been used in industry follow:

- *Alginates*: Colloidal carbohydrate compounds, water-soluble, that thicken ceramic bodies and facilitate pressing and extrusion operations.
- *Camphor*: A whitish, water insoluble material with a melting point of 174°C–197°C. It is soluble in several organic liquids.

- *Cetyl Alcohol*: A water insoluble, white crystalline powder with a melting point of 49.3°C. It also has a lubricating value as a result of its fatty nature.
- *Graphite, Talc, Clay, and Mica*: These are useful lubricants, particularly when finely pulverized, because of their platy nature. The plates tend to slide over one another and also deter sharp, hard particles from being embedded in the die surfaces.
- *Kerosene–Lard Oil*: These mixtures, sometimes known as die oil, can be added directly to dry powders, or else applied to die surfaces. It is the lard oil that provides the lubricating properties. This is a relatively inexpensive lubricant but it probably should not be used where a glaze is to be sprayed on the unfired piece.
- *Lignosulfonates*: An organic material derived from wood pulping that can provide improved plasticity and reduced forming friction. Some lignosulfonate products contain additives to enhance lubrication further and also to function as binders.
- *Methyl Cellulose*: Synthetic gum increases the viscosity of water phases and gives the body increased workability.
- *Mineral Oils*: Petroleum products that have viscosities similar to other orderly liquids.
- *No. 4 Fuel Oil*: A petroleum product of moderate viscosity, which might be used as are kerosene-lard oil mixtures.
- *Polyvinyl Acetate*: Available in powder or emulsion form and can be made to be stable with water.
- *Starches*: Specially prepared for the ceramic industry; reportedly serve as lubricants due to a retained superficial water film.

Lubricant Compatibility

See *compatibility (lubricant)*.

Lubricant Residue

The carbonaceous residue resulting from lubricant that is burned onto the surface of a hot forged part.

Lubricating Grease

Usually a compound of a mineral oil with a soap, lubricating grease is employed for lubricating machinery where the speed is slow or where it would be difficult to retain a free-flowing oil. The soap is one that is made from animal or vegetable oils high in stearic, oleic, and palmitic acids. The lime soaps give water resistance, or a mineral soap may be added for this purpose. Aluminum stearate gives high film strength to the grease. All of these greases are more properly designated as mineral lubricating grease. Originally, grease for lubricating purposes was hog fat or the inedible grades of lard, varying in color from white to brown. Some of these greases were stiffened with fillers of rosin, wax, or talc, which were not good lubricants. The stiffness of such a grease should be obtained with a mineral soap. ASTM specifications for heavy journal bearing grease require 45% soap content. About 2% calcium benzoate increases the melting point. Mineral lubricating grease may contain from 80% to 90% mineral oil and the remainder a lime soap.

Uses

Oronite GA-10, for example, is a sodium salt of terephthalic acid used as a gelling agent in high-temperature greases. It adds water

L

resistance and stabilizes against the emulsion. Ortholeum 300 is a mixture of complex amines, and small amounts added to a grease will give high heat stability. Braycote 617 is a synthetic grease for rockets subject to both heat and cold.

The lubricating grease known as trough grease, used in food plants for greasing trays, tables, and conveyors, contains no mineral oil and is edible.

Lime greases do not emulsify as readily as those made with a soda base and are thus more suitable for use where water may be present.

Graphite grease contains 2%–10% amorphous graphite and is used for bearings, especially in damp places. For large ball and roller bearings a low-lime grease is used, sometimes mixed with a small percentage of graphite. Cylinder grease is made of about 85% mineral oil or mineral grease and 50% tallow. Compounded greases are also marketed containing animal and vegetable oils, or are made with blown oils and compounded with mineral oils. The fatty acids in vegetable and animal oils, however, are likely to corrode metals. Tannin holds graphite in solution, in gear grease *Metaline* is a compound of powdered antifriction metal oxide, and the gums, which is packed in holes in the bearings to form self-lubricating bearings. *Lead-Lube* grease has finely powdered lead metal suspended in the grease for heavy-duty lubrication.

Sett greases are mixtures of the calcium soaps of rosin acids with various grades of mineral oils. They are low-cost semisolid greases used for lubricating heavy gears or for greasing skidways. Clay fillers may be added to improve the film strength, or copper or lead powders may be incorporated for heavy load conditions. *Solidified oil* is also a name given to grease made from lubricating oil with a soda soap and tallow, used for heavy bearings.

Lubrication

(1) The reduction of frictional resistance and wear, or other forms of surface deterioration, between two load-bearing surfaces by the application of a *lubricant*. (2) Mixing or incorporating a lubricant with a powder to facilitate compacting and ejecting of the compact from the die cavity; also, applying a lubricant to die walls and/or punch surfaces.

Lubrication Regimes

Ranges of operating conditions for lubricated *tribosystems* that can be distinguished by their frictional characteristics and/or by the manner and amount of separation of the bearing surfaces. See also *boundary lubrication*, *elastohydrodynamic lubrication*, *full-film lubrication*, *hydrodynamic lubrication*, *quasi-hydrodynamic lubrication*, and *thin-film lubrication*.

Lubricious (Lubricous)

Relating to a substance or surface condition that tends to produce relatively low friction.

Lubricity

The ability of a lubricant to reduce wear and friction, other than by its purely viscous properties.

Lüders Lines

Elongated surface markings or depressions in sheet metal, also visible with the unaided eye, caused by discontinuous (inhomogeneous)

yielding. Also known as *Lüders bands*, *Hartmann lines*, *Piobert lines*, or *stretcher strains*. Lines formed on the surface of components due to uneven deformation when only a portion of the component exceeds the yield point. The lines form the boundary of the yielded zones and traverse the surface as the material continues to yield. Steels having a pronounced yield point are particularly susceptible. The lines are aligned at 45° to the tension axis and are observed on components such as lightly drawn tube and pressed sheet. Although not damaging, they may be unsightly but can usually be prevented by prior uniform light working.

Luggin Probe

A small tube or capillary filled with electrolyte, terminating close to the metal surface under study, and used to provide an ionically conducting path without diffusion between an *electrode* under study and a *reference electrode*.

Luminous

Luminescent emitting light or other radiation by phosphorescence and such phenomenon.

Luminous Flame

A flame that emits significant light due to incandescent carbon particles remaining from incomplete combustion.

Luminous Pigments

Pigments used in paints to make surfaces visible in the dark and in coatings for electronic purposes. They are used for signs, watch and instrument hands, airfield markings, and signals. They are of two general classes. The *permanent* ones are the *radioactive paints*, which give off light without activation, and the *phosphorescent paints*, or *fluorescent paints*, which require activation from an outside source of light. The radioactive paints contain a radioactive element that emits alpha and beta rays, which strike the phosphors and produce visible light. Radium, sometimes used for paints for watch hands, gives a greenish-blue light, but it emits dangerous gamma rays. Also, the intense alpha rays of radium destroy the phosphors quickly, reducing the light. Strontium 90 gives a yellow-green light and has a long half-life of 25 years, but it emits both beta and gamma rays and is dangerous. *Tritium paints*, with a tritium isotope and a phosphor in the resin-solvent paint base, have a half-life of 12.5 years and require no shielding. The self-luminous phosphors for clock and instrument dials contain tritium, which gives off beta rays with only low secondary emission so that the glass or plastic covering is sufficient shielding. Other materials used are *krypton 85*, with a half-life of 10.27 years, *promethium 147*, with a half-life of 2.36 years, and *thallium 204*, with a half-life of 2.7 years.

Fluorescent paints depend upon the ability of the chemical to absorb energy from light and to emit it again in the form of photons of light. This variety usually has a base of calcium, strontium, or barium sulfide and traces of other metal salts to improve luminosity, and the vehicle contains a moisture proof gum or oil. Temporarily luminous paints may be visible for long periods after the activating light is withdrawn. A paint activated by 5 min exposure to sunlight may absorb sufficient energy for 24 h of luminosity. *Luminous wall paints* used for operating rooms to eliminate shadows are made by mixing small amounts of zinc or cadmium sulfide into ordinary

paints. After being activated with ultraviolet rays, they will give off light for 1.5 h.

Phosphorescent paints are lower in cost than radioactive paints and may be obtained in various colors. In general, the yellow and orange phosphorescent pigments are combinations of zinc and cadmium sulfide, the green is zinc sulfide, and the violet and blue pigments are combinations of calcium and strontium sulfides. They are marketed in powder form to be stirred into the paint or ink vehicle, since mixing by grinding lowers the phosphorescence. The natural minerals are not used, as the pigments must be of a high degree of purity, as little as a millionth part of iron, cobalt, or nickel killing the luminosity of zinc sulfide. These phosphorescent pigments are called *phosphors*, but technically they are incomplete phosphors; and copper, silver, or manganese is coprecipitated with the sulfide as an activator or to change the color of the emitted light. The metals that are used as activators are called *phosphorogens*, and their atoms diffuse into the lattice of the sulfide. For fluorescent screens the phosphors must have a rapid rate of extinguishment so that there will be no time lag in the appearance of the events. For television, electron microscope, and radar screens, the phosphors must cease to flow 0.02 s after withdrawal of excitation. They must also be of very minute particle size so as not to give a blurred image. For a white television screen, mixtures of blue zinc sulfide with silver and yellow zinc–beryllium silicates are used. For color television screen is completely covered with a mixture of various colored phosphors, especially rare-earth metal combinations. For scintillation counters for gamma-ray-detection phosphors, the pulses should be of longer duration, and for this purpose crystals of cadmium or cadmium tungstate are used.

Fluorescent fabrics for signal flags and luminescent clothing are impregnated with fluorescent chemicals, which can be activated by an ultraviolet light that is not seen with the eye. Some fluorescent paints contain a small amount of luminous pigment to increase the vividness of the color by absorbing the ultraviolet light and emitting it as visible color. *Fluorescein*, made from phallic anhydride and resorcinol, has the property of fluorescence in a solvent. Since cellulose acetate will keep it in a permanently solid-state, acetate rayon is used as a carrier fabric. Signal panels are distinguishable from a plane at great heights even through a haze, and at night they give a brilliant glow when activated with ultraviolet rays. Fluorescent paints for signs may have a white undercoat to reflect the light passing through the semitransparent pigment. In passing through the color pigments the shorter violet and blue wavelengths are changed to orange, red, and yellow hues, and the reflected visible light is greater than the original light. *Uranine*, the sodium salt of fluorescein, is used by flyers to mark spots in the ocean. One pound (0.45 kg) of uranine will cover 1 acre (4047 m²) of water to a brilliant, yellowish green easily seen from the air. One part of uranine is detectable in 16×10^6 parts of water. *Luminous plastic* for aircraft markings is coated on the inside with radioactive material to give visibility in the dark.

The fluorescent pigments almost always consist of particles of a colorless resin containing a color-fluorescing dye. Two well-known dyes are *Potomac Yellow* and *Alberta Yellow* from Day-Glo Color Corp. and BASF AG makes a series under the trade name *Rhodamine*.

Whitening agents, optical whiteners, or brightening agents, used to increase the whiteness of paper and textiles, are fluorescent materials that convert some of the ultraviolet of sunlight to

visible light. The materials are colorless, but the additional light supplied is blue, and it neutralizes yellow discolorations and enhances the whiteness.

Luminous materials also occur in nature as organic materials, with bioluminescence thought to be a form of chemiluminescence. Fireflies, bacteria, glow worms, and some luminous fish are capable of this feat. It occurs by the mixing of two substances present in the organism; one is *luciferin*, which oxidizes the second, an enzyme known as *luciferase*. The reaction produces an excited form of luciferase, which emits light when it returns to its normal state.

Luster Finish

A bright as-rolled finish, produced on ground metal rolls; it is suitable for decorative painting or plating, but usually must undergo additional surface preparation after forming.

Lute

- (1) A mixture of fireclay used to seal cracks between a crucible and its cover or between container and cover when heat is to be applied.
- (2) To seal with clay or other plastic material.

Lutes

Adhesive substances, usually of earth composition, deriving the name from the Latin *lutum*, meaning “mud.” A clay cement was used by the Romans for cementing iron posts into stone. Although lutes often contain a high percentage of silica sand or clays, the active ingredient is usually sulfur. They may also contain other reactive ingredients such as lead monoxide or magnesium compounds. *Plumber's lutes* are used for pipe joints and seams and for coating pipes to withstand high temperatures. Plaster of paris mixed with a weak glue will withstand a dull-red heat. *Sulfur cements*, or lutes, usually have fillers of silica or carbon to improve the strength. They form a class of acid-proof cements used for ceramic pipe connections. Modern lutes for very high heat resistance do not contain elemental sulfur. Industrial lutes are used for sealing in wires and connections in electrical apparatus, and are compounded to give good bonding to ceramics and metals. A lute cement for adhering knife blades to handles is composed of magnesium acid sulfates, calcined magnesia, with fine silica or powder. The term *sealant* generally refers to a wide range of mineral-filled plastics formulated with a high proportion of filler for application by troweling or air gun.

Lye

Concentrated solutions of either sodium hydroxide or potassium hydroxide.

Lyotropic Liquid Crystal

A type of liquid crystalline polymer that can be processed only from solution.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

Macerate

To chop or shred, as fabric, for use as a filler for a molding resin.

Machinability

The relative ease of machining a metal.

Machinability Index

A relative measure of the machinability of an engineering material under specified standard conditions. Also known as *machinability rating*.

Machinability of Metals

The ease and economy with which a metal may be cut under average conditions is its machinability. Frequently, no truly quantitative assessment is made, but rather a rating or an index is established vis-à-vis a reference material. More quantitative comparisons are based on tool life. For example, maximum cutting speeds for a given tool life may be used as a rating of machinability. Alternatively, tool wear rate may be the basis for a machinability rating. Surface finishes sometimes used for assessing machinability.

Machining Process

The wide range of metal-cutting processes may be represented, with some oversimplification, by the orthogonal cutting process.

Cutting Speed

The machining response of ductile metals is very sensitive to cutting speed. Below about 0.02 m/s, chips form continuously, metal chunks are lifted out of the surface, and the surface is scalloped or pock-marked. When the speed is in the 0.1 m/s range, chips are formed continuously, the shear zone is narrow, and the chip slides on the tools face. Under these conditions, a cutting fluid can lubricate both the rake and flank faces of the tool.

Cutting Fluid

The interaction between the tool and the workpiece is considerably affected by the presence of cutting fluids. Cutting fluid has two primary functions. First, as long as the cutting speed is slow, the cutting fluid can act as a lubricant between the chip and the tool face. Even at higher speeds, some lubricating effect at the flank face may be present. Second, and perhaps more importantly, the cutting fluid serves as a coolant. In most instances, the cutting fluid will be an emulsion of a lubricating phase (oil, graphite, and so on) in water since water is the best heat-transfer medium readily available. Beyond lubrication and cooling, the cutting fluid can be used to flush out the cutting zone.

Surface Quality and Tool Wear

Cutting speed thus affects the all-important machinability considerations of surface quality and tool wear. Surface finish is best with a well-lubricated, moderately low-speed operation or high-speed cutting with no built-up edge. The high pressures and temperatures of operation, abetted by shock loading and vibrations, can lead to rapid tool wear. Tool wear is often sufficiently rapid to make tool replacement a major factor in machining economics. Tools must be replaced when they break or when they have worn to the point of producing an unacceptable surface finish or an unacceptable degree of surface heating.

Metal Properties

A machining operation can be optimized to affect metal removal with the least energy, or the best surface, or the longest tool life, or a reasonable compromise among these factors. Even so, it remains that the optimal ease and economy of machining some alloys is vastly different from that of others, and some basic attributes of easily machined alloys can be set forth.

Toughness

To ensure that chip separation occurs after minimum sliding, low ductility is required. To minimize cutting force, low strength and low ductility combine to mean low toughness. Toughness is generally defined as energy per unit volume consumed en route to fracture. Ironically, materials of maximized toughness are desirable for most engineering applications, and, thus, some of the most attractive alloys, such as austenitic stainless steels, are difficult to machine.

Adhesion

The degree to which the metal adheres to the tool material is important to its machinability.

Actually this attribute can work to advantage or disadvantage. If diffusion results, the tool can be weakened and rapid wear occurs. Otherwise, high adhesion will stabilize the secondary shear zone.

Workpiece Second Phases

Small particles or inclusions in the metal can have a marked effect on machinability. Hard sharp oxides, carbides, and certain intermetallic compounds abrade tooling and accelerate tool wear. On the other hand, soft second phases are beneficial because they promote localized shear and chip breakage.

Thermal Conductivity

In some cases, workpiece thermal conductivity can be important to machinability. A low thermal conductivity generally results in high shear-zone temperature. This can be advantageous in reducing

M

the strength of the metal or in softening second-phase particles. Of course, if adhesion and diffusional depletion of tool alloy content result, the high temperature is a problem. The workpiece temperature can be managed by cutting-speed and cutting-fluid manipulation.

Alloy Systems

Commercial alloys can be grouped into two categories, namely, those designed for ease of machining (so-called free machining grades), and the vast majority, which are of widely varying but generally less than optimum machinability. Considering these latter, ordinary alloys, it can be shown that their machinability may be considerably improved by metallurgical operations that limit strength or ductility or both. Of course, it is not often possible to reduce both strength and ductility simultaneously. Even so, machinability often can be improved by grossly reducing one or the other property.

Machine Forging

Forging performed in upsetters or horizontal forging machines.

Machine Shot Capacity

The maximum weight of thermoplastic resin that can be displaced or injected by the injection (molding) ram in a single stroke.

Machine Welding

Welding with equipment that performs under the continual observation and control of a welding operator. The equipment may or may not load the work. Compare with *automatic welding*.

Machining

Any one of a group of operations that change the shape, surface finish, or mechanical properties of a material by the application of special tools and equipment. Machining almost always is a process in which a cutting tool removes material to affect the desired change in the workpiece. Typically, powered machinery is required to operate the cutting tools.

Although various machining operations may appear to be very different, most are very similar; they make chips. These chips vary in size from the long continuous ribbons produced on a lathe to the microfine sludge produced by lapping or grinding. These chips are formed by shearing away the workpiece material by the action of a cutting tool. Cylindrical holes can be produced in a workpiece by drilling, milling, reaming, turning, and electric-discharge machining (EDM). Rectangular (or nonround) holes and slots may be produced by broaching, EDM, milling, grinding, and nibbling; and cylinders may be produced on lathes and grinders. Special geometries, such as threads and gears, are produced with special tooling and equipment utilizing the same turning and grinding mentioned earlier. Polishing, lapping, and buffing are variants of grinding where a very small amount of stock is removed from the workpiece to produce a high-quality surface.

In almost every case, machining accuracy, economics, and production rates are controlled by the careful evaluation and selection of tooling and equipment. Speed of cut, depth of cut, cutting-tool material selection, and machine tool selection have a tremendous impact on machining. In general, the more rigid and vibration-free a machining tool is, the better it will perform. Jigs and fixtures are often used to support the workpiece. Since it relies on the

plastic deformation and shearing of the workpiece by the cutting tool, machining generates heat that must be dissipated before it damages the workpiece or tooling. Coolants, which also act as lubricants, are often used.

Boring

This machining operation increases the size of an existing hole in a workpiece. The usual purpose of boring is to produce a hole with an accurate diameter and good surface finish. Boring can be performed on a special machine or a lathe, with either the workpiece or the boring tool being on a movable table. A rotating spindle, holding either a single-point cutting tool or the workpiece, is fed into the work. As the spindle rotates, the cutting tool engages the interior of the existing hole, and chips are formed as a tool cuts into the workpiece. The actual cutting action of a boring tool is very similar to a lathe turning tool.

Broaching

This is the removal of material to produce a slot (or other formed shape) in a workpiece by moving a multiple-tooth, barlike tool across the workpiece. The cutting action results from the configuration of each tooth being progressively higher than the preceding one. Tooth of the brooch removes a small, predetermined amount of stock, the chip. Broaching is a very economical machining operation, although tool costs can be high; accordingly, it is applied most often to high-volume production.

Drilling

One of the most common machining operations, drilling is a method of producing a cylindrical hole in a workpiece. A typical twist drill consists of a helically grooved steel rod with two cutting edges on the end. The helical flutes or grooves in the drill allow the chips to be removed from the cutting edge, conduct coolant to the cutting lips, and form part of the cutting-edge geometry. Although drills may appear to be simple, their geometries are carefully controlled. Drilling is a very fast and economical process, but it usually does not produce a very accurate hole diameter or a fine surface finish.

Turning

This type of machining is performed on a lathe. The process involves the removal of material from a workpiece by rotating the workpiece under power against a cutting tool. The cutting tool is held in a tool post that is supported on a cross slide and carriage. The tool may be moved radially or longitudinally in relation to the turning axis of the workpiece. Forms such as cones, spheres, and related workpieces of concentric shape as well as true cylinders can be turned on a lathe.

The most common lathe is an engine, where the workpiece may be rotated and held between tapered centers or by means of a collet or chuck. A turret lathe is an engine lathe that has a multisided indexing tool holder or turret instead of a rail stock center. This adds to the versatility of the machine by allowing a greater variety of cutting tools to be applied to the rotating workpiece.

Automatic Screw Machines

Automatic screw machines are sophisticated lathes that have been designed to perform several turning operations automatically in

rapid succession without removing the workpiece from the machine. They are used when the volume and complexity of the required workpieces justify the expense of setting up and operating these very versatile but complex machines. A screw machine (named for the screw manufacturing role for which it was created) is cam-controlled or driven by computer numerical control (CNC).

Milling

This process removes material by feeding a workpiece through the periphery of a rotating circular cutter. Each tooth of the rotating multitoothed milling cutter removes a portion of material from the passing workpiece.

Milling cutters are designed for particular operations and are classified as either shell type or end type. Shell mills are disk shaped and usually produce continuous slots. When well supported in the machine tool to minimize vibration, they perform well and economically. The more versatile end mill is held by its shank only. End mills can be used for slotting just like a shell mill, but they also can cut pockets, contours, and even cylindrical holes. End mills with four or six flutes are stronger and more rigid than two-flute mills, and so are better able to machine tougher materials.

Reaming

This machining operation enlarges an existing hole by a few thousandths of an inch and produces a hole whose diameter is very accurately controlled. The cutting edges of a reamer may be ground on the apexes between longitudinal flutes or grooves, or cutting may take place on chamfered edges at the end of the reamer. Reaming is performed either manually or by machine, often as a finishing operation after drilling. Reamed holes have good surface finish.

Sawing

This is the parting of material by using blades, bands, or abrasive disks as the cutting tools. In the most common type of saw, a toothed blade is passed across the workpiece in either a reciprocating or continuous motion. The teeth can be mounted on continuous bands, short steel blades, or the periphery of a disk. Friction sawing is a rapid process used to cut steel as well as certain plastics. A very high-speed blade softens the workpiece material with frictional heat. The material is then wiped away from the workpiece by the cutting blade. Since many teeth engage the workpiece, no single tooth overheats. Abrasive sawing looks similar to friction sawing, except that a thin rubber or bakelite bonded abrasive disk grinds the material away instead of simply softening and wiping it.

Nibbling

Nibbling is the operation that cuts away small pieces of material by the action of a reciprocating punch. A nibbler takes repeated small bites from the workpiece (which is usually a thin sheet of material) utilizing a quickly reciprocating punch system. As the work is passed beneath the punch, a small nibble of material is removed by the punch during each punch cycle. After each quick nibble, the workpiece is advanced under the punch to allow another small bite to be taken away. In this manner, a great deal of material can be removed from the workpiece after several tens or hundreds of individual punching cycles.

Shaping

The process cuts flat or contoured surfaces by reciprocating a single-point tool across the workpiece. The tool is mounted on a hinged unit known as a clapper box, which lifts up to disengage the tool from the surface on the return stroke. The cutting action of a shaper is actually similar to turning, except that the single-point cutting tool moves straight across a workpiece, instead of having the workpiece rotate against the cutting tool.

Grinding

This process removes material by the cutting action of a solid rotating, grinding wheel. The abrasive grains of the wheel perform a multitude of minute machining cuts on the workpiece. Although grinding is sometimes used as the sole machining operation on a surface, it is generally considered a finishing process used to obtain a fine surface and extremely accurate dimensions.

Grinding is used to machine a wide range of metals, carbide materials, stone, and ceramics. The grinding process may be used on metals too hard to machine, otherwise because commercial grinding abrasives are many times harder than the metals to be machined.

Grinding wheels are composed of abrasive grains plus a bonding material. The wheels are often very porous, with homogeneous open areas between the grains. The abrasives most commonly used are silicon carbide and aluminum oxide. Coarse-grained wheels are used for rapid removal of stock; wheels with fine grains cut more slowly but give smoother finishes. Coolants are applied to the grinding point to dissipate the heat generated and to flush away the fine chips.

Honing

Honing is a grinding process that removes a small amount of material from a workpiece by means of abrasive stones. It is able to produce extremely close dimensional tolerances and very fine surface finishes. The abrading action of the fine-grit stones occurs on a wide surface area rather than on a line of contact as in grinding.

Lapping

This is a precision abrading process used to finish a surface to a desired state of refinement or dimensional accuracy by removing an extremely small amount of material. Lapping is accomplished by abrading a surface with a fine abrasive grit rubbed about it in a random manner. A loose unbonded grit is used. It is traversed about on a lap, made of a somewhat softer material than the workpiece. The unbonded grit is mixed with a vehicle such as oil, grease, or soap and water.

Polishing

This is a smoothing of a surface by the cutting action of an abrasive grit that is either glued to or impregnated in a flexible wheel or belt. Polishing is not a precision process; it removes stock until the desired surface condition is obtained.

Superfinishing

For a mirror-like surface, a precision abrading process known as superfinishing is used. Superfinishing removes minute flaws or inequalities because it is performed with an extremely fine-grit abrasive stone, shaped to match and cover a large portion of work surface.

M

Buffing

This is the smoothing and brightening of a surface by rubbing it with a fine abrasive compound carried in a soft wheel or belt. The abrasive is a fine powder or flour mixed with tallow or wax to form a smooth paste. Buffing is performed on the same type of machines as polishing; frequently, both buffing and polishing wheels are included on the same machine. Buffing differs from polishing in that a finer grit is used and less material is removed from the workpiece.

Ultrasonic Machining

In this process, material is removed by abrasive bombardment and crushing in which a vibrating tool drives an abrasive grit against the workpiece. In ultrasonic machining, the tool never directly contacts the workpiece; rather, the vibrations (typically 20,000 Hz) drive the abrasive, which is suspended in a liquid, against the workpiece. Impressions may be economically sunk in glass, ceramics, carbides, and hard brittle metals by this method. The shape of the tool basically determines the shape of the impression.

Electric-Discharge Machining

This is a machining process in which electrically conductive materials can be removed by repeated electric sparks. EDM is used to form holes of varied shape and materials of poor machinability. Unlike other machining operations, it does not rely on a cutting tool to shear away the workpiece. Instead, it uses electrical energy to melt or vaporize small areas on the workpiece. The sparks created by an EDM unit (at a rate greater than 20,000 per second) are discharged through the space between the tool (cathode) and the workpiece (anode). The small gap between the tool and workpiece is filled with a circulating dielectric hydrocarbon oil, which serves as a cooling medium and flushes away metal particles. Although not as fast as other machining processes, EDM has the unique ability to remove hard materials that otherwise would not be machinable.

Machining Allowance

See *finish allowance*.

Machining Damage (Ceramics and Glasses)

A typical or excessively large surface microcracks or damage resulting from the machining process; for example, striations, scratches, and impact cracks. Small surface and subsurface damage is intrinsic to the machining damage.

Machining Damage (Metals)

See *surface alterations* (metals) and *surface integrity* (metals).

Machining Stress

See *Residual stress* caused by machining.

Machining, High Speed

Machining operations such as turning, milling, and drilling involve the modification of a workpiece through the removal of material. In machining of metals, this material removal occurs via a concentrated shear flow initiated at the point of contact between the

workpiece and a wedge-shaped tool (e.g., turning insert and milling flute) to produce a chip and a machined surface. The cutting action is generated by the rotation of the machine spindle. Increasing the power and speed of the spindle and axes has several advantages, which include (1) shorter machining time, (2) improved surface finish, (3) reduced thermal and mechanical stresses on the workpiece and tool, and (4) increased dynamic stability. These potential advantages have driven a recent, rapid increase in the industrial adoption of high-speed machining processes and technology.

The definition of high-speed machining is not static but instead changes with time depending on available tool materials and machine technology. Reliable machining spindles capable of running continuously at speeds of up to 40,000 revolutions per minute (rpm) with a power output of 30 kW are now available on production equipment. In addition, axis speeds of production machining centers now exceeded 60 m/min with accelerations of greater than 1g (g = gravitational acceleration 9.8 m/s²). The marked increase in material removal rates and the reduction in production time and costs afforded by this new technology have the potential of revolutionizing the manufacturing process. However, because of rapid tool wear, not all materials can be machined at high speeds. In general, machining speeds on difficult-to-machine materials such as titanium and hardened steel are limited by the availability of suitable tool materials, whereas machining speeds and more machinable material such as aluminum and plastic are limited by the available machine technology.

Tooling Materials

The increased use of high-speed machining has been enhanced by the development of suitable tool materials. In general, the higher the yield strength and melting temperature of the material being machined, the greater the stresses and temperatures that will be generated at the tool-chip interface. These increased stresses and temperatures cause increased rates of chemical and mechanical tool wears, but with the introduction of Al₂O₃-TiC, silica nitride, and SiC whisker-reinforced Al₂O₃ ceramic cutting tools, the high-speed machining of certain materials becomes practical. Speeds as high as 5000 sfm have been reported, and speeds 1000–3000 sfm are routine with essentially pure ceramics (i.e., low metallic impurities). However, the older cermets (ceramic-coated cemented carbides) have been limited to speeds below 1400 sfm. This is because plastic deformation of the metallic phase in these carbides occurs at temperatures as low as 600°C, which limits the cutting speed.

High toughness, strength, and thermal conductivity result in tools that have improved resistance to chipping, which makes it possible to do interrupted cutting when machining metal. High hardness generally correlates with improved wear resistance, although chemical compatibility is essential for good performance. Since temperatures can be extremely high at the tools/workpiece interface, it is important to retain high hardness and toughness as the temperature increases. The greater efficiency of many ceramics, compared with cermets, is that they maintain wear resistance (i.e., hardness) and strength at these elevated temperatures.

Controllers: Data Processing

The increased complexity of machined parts leads to a similar increase in the size and complexity of the programs required to generate necessary machine motion. The flow rate of the data required to control tool motions over complex surfaces has grown dramatically as spindle speeds have increased. This is especially true as high-speed machining becomes practical in the die

and mold industry, where the tool motion over the workpiece is described in a series of point-to-point movements and the volume of data required to geometrically define a part is quite large. As a result, machine tool controllers must be able to store large amounts of data and process the data quickly. Most high-speed machines are now equipped with large memories, powerful computers, and network connections.

Macro

In reinforced plastics, the gross properties of a composite as a structural element without consideration of the individual properties are the identity of the constituents.

Macroetching

Etching a metal surface to accentuate gross structural details, such as grain flow, segregation, porosity, or cracks, for observation by the unaided eye or at magnification to 25 $\times$.

Macrograph

A graphic representation of the surface of a prepared specimen at a magnification not exceeding 25 $\times$. When photographed, the reproduction is known as a photomacrograph.

Macrohardness Test

A term applied to such hardness testing procedures as the Rockwell or Brinell hardness tests to distinguish them from microindentation hardness tests such as the Knoop or Vickers tests. See also *microindentation* and *microindentation hardness number*.

Macropore

Pores in pressed or sintered powder compacts that are visible with the naked eye.

Macroscopic

Visible at magnification at or below 25 $\times$.

Macroscopic Stress

Residual stress in a material in a distance comparable to the gauge length of strain measurement devices (as opposed to stresses within very small, specific regions, such as individual grains). Compare with *microscopic stress*.

Macroshrinkage

Isolated, clustered, or interconnected voids in a casting that are detectable macroscopically. Such voids are usually associated with abrupt changes in section size and are caused by feeding that is insufficient to compensate for solidification shrinkage.

Macroslip

A type of sliding in which all points on one side of the interface are moving relatively to those on the other side in a direction parallel to the interface. See also *microslip*.

Macrostrain

The main strain over any finite gage length of measurement large in comparison with interatomic distances. This can be measured by several methods, including electrical-resistant strain gages and mechanical or optical extensometers. Elastic macrostrain can be measured by x-ray diffraction.

Macrostress

Same as *macroscopic stress*.

Macrostructure

The structure of metals as revealed by macroscopic examination of the etched surface of a polished specimen.

Magnesia

A fine, white powder of **magnesium oxide**, MgO, obtained by calcining magnesite or dolomite and refining chemically and use principally in *basic refractories*. It is used in pharmaceuticals, in cosmetics, in rubbers as a scorch-resistant filler, in soaps, and in ceramics. The powder is converted from magnesium hydroxide. **Maglite**, of Whittaker, Clark and Daniels, Inc., used for rubbers, is produced from seawater. **Magox magnesia**, of Basic Chemicals, is 98% pure MgO extracted from seawater. It comes in particle sizes to 325 mesh and high- and low-activity grades for rubber, textile, and chemical uses. A very pure magnesia is also produced by reducing magnesium nitrate.

Magnesia ceramic parts, such as crucibles and refractory parts, are generally made from magnesia that is usually electrically fused and crushed from the large cubic crystals. The crystals have ductility and can be bent. The particle size and shape are easily controlled in the crushing to fit the needs of the molded article. Pressed and sintered parts have a melting point of about 5070°F (2765°C) and can be employed to 4172°F (2300°C) in oxidizing atmospheres or to 3092°F (1700°C) in reducing atmospheres. The material is inert to molten steels and two basic slags. Magnafrax 0340, of Carborundum Co., is magnesia in the form of plates, tubes, bars, and disks. The material has a specific gravity of 3.3 and a thermal conductivity twice that of alumina. Its vitreous structure gives it about the same characteristics as a single crystal for electronic purposes. Magnorite, of Norton Co., is fused magnesia in granular crystals with a melting point of 5072°F (2800°C), used for making ceramic parts and for sheathing electric heating elements. **K-Grain magnesia**, of Kaiser Aluminum and Chemical Corp., is 98% magnesia, containing no more than 0.4 silica. The magnesium ceramic, of Corning Inc., is 99.8% pure.

Magnesia refractory brick consists mainly of the mineral periclase (MgO) and is available in chemically bonded, pitch-bonded, burned or fired, and burned and pitch-impregnated forms. Historically, natural magnesite (MgCO₃) that was calcined provided the raw material for this brick, but with the increased demands for higher temperatures and the introduction of fewer process impurities, more high-purity magnesia from seawater or underground brines has been used. In the seawater and brine processes, the magnesia is obtained by calcining precipitated Mg(OH)₂, which provides MgO of purity up to 98%. See also *refractories*.

Magnesite

A white to bluish-gray mineral used in the manufacture of bricks for basic refractory furnace linings and as an ore of magnesium.

M

The ground, burned magnesite is a light powder, shaped into bricks at high pressure and baked in kilns. Magnesite is a magnesium carbonate with some iron carbonate and ferric oxide. Magnesite releases carbon dioxide on heating and forms magnesia. When heated further, it forms a crystalline structure known as *periclase*. The fused magnesia made in the arc furnace is actually synthetic periclase. The synthetic material is in transparent crystals up to 2 in. (5 cm), which are crushed to powder for thermal insulation and for making refractory parts. Magnesite in compact, earthy form or granular masses has a vitreous luster, and the color may be white, gray, yellow, or brown. Mohs hardness is 3.5–4.5, and a specific gravity is about 3.1.

The product known as *dead-burned magnesite* is in the form of dense particles used for refractories. It is produced by calcining magnesite at 2642°F–2732°F (1450°C–1500°C). Caustic magnesite is a product resulting from calcination at 1292°F–2192°F (700°C–1200°C), which leaves from 2% to 7% carbon dioxide in the material and gives sufficient cementing properties for use as a refractory cement.

Magnesite for use in producing magnesium metal should have at least 40% MgO, with not over 4.5% CaO and 2% FeO. Magnesite is a valued refractory material for crucibles, furnace brick and linings, and high-temperature electrical insulation because of its basic character, chemical resistance, high softening point, and high electrical resistance. Its chief disadvantage is its low resistance to heat shock. Magnesite brick and refractory products are marketed under a variety of trade names, such as *Ritex*, of General Refractories Co., and *Ramix*. It is also used as a covering for hot piping. The German artificial stone called *Kunststein* is magnesite.

Magnesium and Alloys

A silvery-white metal, symbol Mg, magnesium is the lightest metal that is stable under ordinary conditions and produced in quantity. It is the sixth most abundant element, with a specific gravity of 1.74, melting point 650°C, boiling point about 1110°C, and electrical conductivity about 40% that of copper. Ultimate tensile strengths are about 90 MPa as cast, at least 158 MPa for annealed sheet, and 179 MPa for hard-rolled sheet, with corresponding elongations of about 4%, 10%, and 15%, respectively. The strength is somewhat higher in the forged metal. Magnesium has a close-packed hexagonal structure that makes it difficult to roll cold, and its narrow plastic range requires close control in forging. Repeated reheating causes grain growth. Sheet is usually formed at 150°C–200°C. It is the easiest to machine of the metals.

Characteristics

The excellent machinability of magnesium makes its use economical in parts where weight saving may not be of primary importance, but where much costly machining is required. Such parts, when made of magnesium, can be machined at higher speeds and with greater economy than would be possible with most other commonly used metals. Chemical milling can be used on magnesium.

Magnesium can be cast and fabricated by practically every method known to the metal worker. The metal is cast in sand or permanent molds to obtain lightweight castings with good strength, stiffness, and resistance to impact or shock loading. Magnesium sand and permanent-mold castings are heat treatable to further improve mechanical properties.

The die-casting process is similarly applicable to magnesium, and this method of casting should always be considered when the quantities desired are in the range that indicates its use. Both hot and cold chamber processes are usable.

The metal can also be cast by some of the less common methods, including plaster mold, centrifugal, shell molding, and investment processes.

Magnesium is rolled into sheet and plate and can be extruded into rods, bars, tubing, and an almost endless variety of structural and special shapes.

Sheet and extrusions are very easily formed using techniques that have been developed especially for magnesium. Stamping, deep and shallow drawing, blanking, coining, spinning, and impact extrusion are just a few of the production forming operations regularly used on magnesium, and these indicate the adaptability of the metal to a large variety of metal working procedures.

The forging of magnesium is accomplished by methods much the same as those used for forging other metals. Both press and hammer equipment are used, but the former is most commonly employed because the physical structure of magnesium makes the metal better adapted to the squeezing action of the forging press. Magnesium forgings are chosen when a high strength-to-weight ratio, rigidity, or pressure tightness is required. The selection of forging, however, is governed by the fact that, like permanent mold and die castings, a sufficient number of parts must be needed to justify the cost of die equipment.

Magnesium parts can be joined by any of the common methods. Arc and electric-resistance welding, adhesive bonding, and mechanical fastening are in daily production use. Brazing and gas welding, although not as frequently used as the other methods, are also suitable ways of joining magnesium.

Magnesium possesses relatively high thermal and electrical conductivities, very high damping capacities, and is nonferromagnetic. It has good stability to atmospheric exposure and good resistance to attack by alkalis, chromic and hydrofluoric acids, and many organic chemicals, including hydrocarbons, aldehydes, alcohols (except methyl), phenols, amines, esters, and most oils. Bare magnesium surfaces are nonsticking (snow, ice, sand, etc.) and nonmarking. Magnesium also has a low sparking tendency.

Magnesium develops a corrosion-inhibiting film upon exposure to clean atmospheres and fresh water, but that film breaks down in the presence of chlorides, sulfates, and other media, necessitating corrosion protection in many applications. Many protective treatments have been developed for this purpose. It is also rapidly attacked by mineral acids, except chromic and hydrofluoric acids, but is resistant to dilute alkalis; aliphatic and aromatic hydrocarbons; certain alcohols; and dry bromine, chlorine, and fluorine gases. Anodized magnesium is produced by immersing in a solution of ammonium fluoride and applying a current of 120 V. The fluoride film has a thickness of only 0.0003 cm, but it removes cathodic impurities from the surface of the magnesium, giving greater corrosion resistance and also better paint adhesion.

Magnesium is valued chiefly for parts where light weight is needed. It is a major constituent in many aluminum alloys, and very light alloys have been made by alloying magnesium with lithium.

The pure metal ignites easily, and even when alloyed with other metals, the fine chips must be guarded against fire. In alloying, it cannot be mixed directly into molten metals because of flashing, but is used in the form of master alloys. The metal is not very fluid just above its melting point, and casting is done at temperatures considerably above the melting point so that there is danger of burning and formation of oxides. A small amount of beryllium added to magnesium alloys reduces the tendency of the molten metal to oxidize and burn. The solubility of beryllium in magnesium is only about 0.05%. As little as 0.001% lithium also reduces fire risk in melting and working the metal. Molten magnesium decomposes water so that green-sand molds cannot be used because explosive

hydrogen gas is liberated. For the same reason, water sprays cannot be used to extinguish magnesium fires. The affinity of magnesium for oxygen, however, makes the metal a good deoxidizer in the casting of other metals.

Production

Magnesium is produced commercially by the electrolysis of a fused chloride, or fluoride obtained either from brine or from a mineral ore, or it can be vaporized from some ores.

These two major methods of producing magnesium are used throughout the world. These can be seen in Figures M.1 and M.2 (electrolytic and the silicothermic processes). In the electrolytic process, the electrolysis of magnesium chloride to yield chlorine and metallic magnesium is the basis of this process. Although magnesite, dolomite, and natural brines have been used as raw materials, the principal source is seawater, which contains about 0.13% magnesium.

The ferrosilicon process (silicothermic) was developed commercially during the World War II in Canada.

Alloys and Alloy Designation

Although magnesium alloys are moderate in strength and rigidity, they have high specific strength and rigidity because of their low density, which, as it is in the range of 1771–1827 kg/m³, is the lowest of common metals. Modulus of elasticity in tension is typically 44,800 MPa, and ultimate tensile strength ranges from 152 to 379 MPa, depending on the alloy and form. Both wrought and cast alloys are available, the former in sheet, plate, rod, bar, extrusions, and forgings, and the latter for sand, permanent-mold, investment, and die castings. Alloys are designated by a series of letters and numbers followed by a temper designation. The first part of the

alloy designation indicates by letters the two principal alloying elements (or one if the alloy contains only one alloying element: A for aluminum, E, rare earth elements; H, thorium; K, zirconium; M, manganese; Q, silver; S, silicon; T, tin; and Z, zinc. The two (or one) numbers that follow indicate the amount (in percent rounded off to whole numbers) of these elements. These numbers are followed by a letter to distinguish among alloys having the same amount of these alloying elements. The temper designations that follow are similar to those for aluminum alloys; F (as fabricated); O (annealed); H10 and H11 (slightly strain hardened); H23, H24, and H26 (strain hardened and partially annealed); T4 (solution heat treated); T5 (artificially aged); T6 (solution heat treated and artificially aged); and T8 (solution heat treated, cold worked, and artificially aged). Thus, AZ91C-T6 is the designation for an alloy containing 8.7% aluminum and 0.7% zinc as the major alloying elements. The letter C indicates that it is the third such alloy to be standardized, and, in this case, it is the solution heat-treated and artificially aged temper. These designations, however, do not distinguish between wrought and cast alloys.

In addition to AZ91C, other magnesium sheet and plate alloys include AZ31B, HK31A, and HM21A, of which AZ31B is the strongest at room temperature and the most commonly used. In the H24 temper, it has an ultimate tensile strength of 290 MPa, a tensile yield strength of 220 MPa, 15% elongation and be used at service temperatures to about 93°C. The others, however, especially HM21A, are more heat resistant and can sustain temperatures to about 315°C. For HM21A, the 100 h creep strength for 0.1% deformation is 86 MPa at 214°C and 52 MPa at 316°C. None of the alloys are especially formable, with a minimum bend radii for AZ31B-O, the most formable, ranging from about five times thickness (5T) at room temperature to 2T at 260°C. Thus, heat is often required in forming operations, especially deep-drawing.

AZ31B is also widely used in the form of bar and other extruded shapes. The alloys for bar in extruded shapes are generally of two kinds: those alloyed principally with aluminum and zinc, and those alloyed with zinc and a bit of zirconium. In the former, strength increases with increasing aluminum content, and in the latter with increasing zinc content. Some of each kind responds to artificial aging, providing in the T5 temper ultimate tensile strengths in the 345–379 MPa range. AZ31B and many of the alloys for bar and extrusions are also suitable for forging. The hot-working range may be as low as 232°C–371°C or 293°C–538°C.

There are several magnesium die-casting alloys but more than a dozen magnesium sand casting alloys and magnesium permanent-mold casting alloys. One composition, AZ91, is available in four grades; AZ91A, B, C, and D. AZ91C, for sand- and permanent-mold castings, contains 8.7% aluminum, as opposed to 9% in the die-casting alloys (A and B). Each also contains 0.7% zinc and 0.13% manganese. As die-cast, AZ91A and AZ91B provide an ultimate tensile strength of 228 MPa, a tensile yield strength of 152 MPa, and 24% elongation. For AZ91C-T6, these values are 276 MPa, 145 MPa, and 6%, respectively. AZ91D is a high-purity version, containing extremely low residual contents of iron, copper, and nickel, which markedly improves corrosion resistance, precluding the need for protective treatments in certain applications, such as auto underbody parts. The benefits of high purity are apparently applicable to other alloys as well, such as AS41, a more heat-resistant die-casting alloy.

The sand- and permanent-mold casting alloys generally use either aluminum, zinc, and manganese or zinc, thorium, zirconium, and, in some cases, silver and rare earth elements, as alloying elements. Almost all these alloys respond to artificial aging or solution heat treating and artificial aging. The strongest, ZE63A, in the T6

FIGURE M.1 The electrolytic extraction of magnesium from seawater. (From Schwartz, M., ed., *McGraw-Hill Encyclopedia of Science and Technology*, Vol. 10, McGraw-Hill, New York, 1992, p. 295. With permission.)

temper, and ZK61A, in the T5 or T6 temper, have an ultimate tensile strength of about 310 MPa, a tensile yield strength of about 193 MPa, and about 10% elongation. The alloys containing zirconium and rare earth elements—ZE33A, ZE41A, and ZE63A—are more creep resistant at higher temperatures than the aluminum-, zinc-, and manganese-bearing alloys, but are more difficult to cast. The magnesium–silver-bearing alloys, QE22A and QH21A, also are superior in elevated-temperature performance, have good cast ability and weldability, but are quite costly.

Like their base metal, magnesium alloys have outstanding machinability, providing faster cutting speeds and greater depths of cut at less power than all commonly machined metals. However, dust, chips, and turnings can pose a fire hazard, necessitating special precautions.

Although lithium is no longer used in magnesium alloys, a series of magnesium–lithium alloys, developed in the past for aerospace applications and ammunition containers, were noted for their extremely light weight and moderate ultimate tensile strengths—100–248 MPa. One such alloy is LA141A, at a density of only 1245 kg/m³, or three quarters that of magnesium.

Magnesium–nickel is a master alloy of magnesium and nickel used for adding nickel to magnesium alloys and for deoxidizing nickel and nickel alloys. One such alloy, contains about 50% of each metal, is silvery white in color, and is furnished in round bar form. Magnesium–Monel contains 50% magnesium and 50% Monel metal. Alloys of magnesium with nickel, Monel, zinc, copper, or aluminum, used for deoxidizing nonferrous metals, are called stabilizer alloys.

Properties

Magnesium–aluminum–zinc alloys often have sufficient strength to give satisfactory service at temperatures as high as 177°C. For still higher-temperature services (and sometimes lower-temperature service), the alloys especially developed for such service are usually required. These are the magnesium–rare earth metal and the magnesium–thorium alloys. They have good short-time mechanical strength, good strength under long-time loading (creep strength), and good modulus of elasticity, at these higher temperatures. In addition, they retain these good properties throughout long exposures to elevated temperatures.

Magnesium alloys are similar to other nonferrous alloys in that they do not exhibit a definite endurance limit when subjected to fatigue loading. Instead, their fatigue strength continues to drop as the required life of the part increases. But the “signal–noise curves” for magnesium are much more horizontal at long lives than the curves of aluminum alloys, for example. Therefore, magnesium alloys are especially suited to applications requiring a high number of cycles of fatigue loading.

All magnesium alloys have excellent damping capacity compared to the same form in other metals. As with other metals, sand castings have the highest, die castings have lower, and the wrought forms have the lowest damping capacity.

K1A

A magnesium–zinc alloy, K1A, was developed to give the greatest damping capacity in an alloy that has improved castability and better strength.

K1A magnesium casting alloy gives the greatest damping capacity in both sand and die castings. Where greater strength is required, especially creep strength, the elevated-temperature casting alloys can be used, as they have about the next highest damping capacity.

EZ33A-T5 sand castings where rare earth metals and zirconium with or without zinc are added to magnesium, results in casting alloys for use at temperatures falling roughly between 177°C and 260°C. This alloy is often used for its high damping capacity combined with good strength.

It has damping capacity comparable to that of gray cast-iron. The magnesium–zinc–zirconium and the magnesium–aluminum–zinc casting alloys have lower, but still good, damping capacity. No special high-damping wrought alloys have been developed, as the common alloys, AZ31B and ZE10A sheet and AZ31B extrusions, already have as high damping capacity as appears possible for wrought magnesium alloys.

Applications

Reviewing the nonstructural uses of magnesium provides an accurate perspective of the entire industry. Nonstructural uses are those in which magnesium is used for its particular chemical, electrochemical, and metallurgical properties. The principal nonstructural uses are as an alloying constituent in other metals (principally aluminum); nodularizing agent for graphite in cast-iron; reducing agent in the production of other metals, such as uranium, titanium, zirconium, beryllium, and hafnium; desulfurizing agent and iron and steel production; sacrificial anode in the protection of other metals against corrosion; and anode material in reserve batteries and dry cells.

As structural materials, magnesium alloys are best known for their light weight and high strength-to-weight ratio. Accordingly, they are used generally in applications where weight is a critical factor and where high mechanical integrity is needed.

Some automobiles contain magnesium parts such as the distributor diaphragm, steering column brackets, and a lever cover plate. Magnesium alloy die castings are also used on chainsaws, portable power tools, cameras and projectors, office and business machines, tape reels, sporting goods, luggage frames, and many other products.

Use of sand and permanent-mold castings are confined largely to aircraft engine and airframe components. Engine parts include gear boxes, compressor housings, diffusers, fan thrust reversers, and miscellaneous brackets. On the airframe, magnesium sand castings are used for leading edge flaps, control pulleys and brackets, and entry door gates, and various cockpit components.

Magnesium is used extensively in wheels, auxiliary equipment, flooring, seating, electronic and instrument cases, etc. Other military uses are in ground handling equipment for aircraft and missiles, ordinance equipment such as vehicles and weapons, and portable shelters and hand-carried communications equipment.

In ground transportation vehicles, both military and commercial, magnesium is used in the engines, transmissions, differentials, pumps, and other parts of the power plant. It has also been used in the floors and body panels of trucks and trailers, while for many years magnesium wheels have been used on all the Indianapolis “500” racing cars.

Additionally, the use of magnesium wrought products has become rather limited. Magnesium sheet, extrusions, and forgings continue to be used in a few limited airframe applications. The temperature alloys are used in at least 20 different missiles (including ICBMs) and on various spacecraft.

In consumer goods, magnesium is used in a wide variety of equipment. Among the household goods in which magnesium is

used are portable appliances, furniture, luggage, griddles, ladders, and lawn mowers. Among types of office equipment that use magnesium are typewriters, dictating machines, adding machines, calculators, and furniture. In sporting goods, magnesium is used in such items as sleds, high-jump and pole vault cross bars, and baseball masks. Magnesium is also used in instruments and for such items as binoculars and camera bodies.

Because of its rapid, yet controlled, etching characteristics as well as its lightness, strength, and wear characteristics, magnesium finds usage in photo-engraved printing plates.

In addition to the many structural uses, magnesium has several nonstructural uses. A large nonstructural use is in the cathodic protection of other metals from corrosion. It also functions well in dry-cell battery construction. Magnesium also has chemical and metallurgical uses. Among these are the Grignard reaction; pyrotechnics; high-energy fuels; alloying in aluminum, zinc, and lead alloys; and as an additive in the manufacture of nodular cast iron, lead, nickel alloys, and copper alloys. It is also used in the production of titanium, zirconium, beryllium, uranium, and hafnium.

Magnesium Carbonate

A white, insoluble powder of composition MgCO_3 , containing also water recrystallization. The specific gravity is 3.10. It is made by calcining dolomite with coke, slaking with water, saturating with carbonic acid gas, and crystallizing out the magnesium carbonate. It is employed as an insulating covering for steam pipes and furnaces, for making oxychloride cement, in boiler compounds, and as a filler for rubber and paper. *Montax*, used as a filler, is a mixture of hydrated magnesium carbonate and silica powder. Magnesium carbonate is a good heat insulator because of the great number of microscopic dead-air cells in the material. The insulating material known as 85% magnesia has a density of 192 kg/m³. Hydrated magnesium carbonate is a fine, white powder called **magnesia alba levis**, slightly soluble in water, and used in medicine.

Magnesium Oxide

Magnesium oxide (MgO) is a synthetic mineral produced in electric arc furnaces or by sintering of amorphous powder (periclase). Refractory applications consume a large quantity of MgO. Both brick and shapes are fabricated at least partially of sintered grain for use primarily in the metal-processing industries. Heating unit insulation is another major application for periclase. Principal advantages of periclase are its thermal conductivity and electrical resistivity at elevated temperatures.

Specialty crucibles and shapes also are fabricated from MgO. These are used in pyrometallurgical and other purifying processes for specialty metals. Both slip-casting and pressing techniques are employed to manufacture shapes.

Thermocouple insulation comprises still another outlet for periclase. Since most of these go into nuclear applications, a high-purity product is required. MgO is also an important glaze constituent.

Single crystals of MgO have received attention because of their use in ductile ceramic studies. Extreme purity is required in this area. Periclase windows are also of potential interest in infrared applications because of their transmission characteristics.

Magnesium Sulfate

A colorless to white, bitter-tasting material occurring in sparkling, needle-shaped crystals of composition, $\text{MgSO}_4 \cdot 7\text{H}_2\text{O}$. The natural

M

mineral was called *epsomite*, from an Epsom Spa, Surrey, England. In medicine, it is called *epsom salt*. It is used in leather tanning, as a mordant in dyeing and printing textiles, as a filler for cotton cloth, for sizing paper, in water-resistant and fireproof magnesia cements, and as a laxative. It has been sold and canisters as a heat-storage medium for solar energy by Pfizer Co. It can also be obtained in the anhydrous form as a white powder. The specific gravity of the hydrous material is 1.678 and of the anhydrous 2.65. It occurs naturally as deposits from spring waters and is also made by treating magnesite with sulfuric acid.

Magnet Wire

Insulated wire for the winding of electromagnets and for coils for transformers and other electrical applications. Since compactness is usually a prime consideration, *high-conductivity copper* is used in the wire, but where weight saving is important, aluminum wire may be used and has the advantage that an extremely thin, anodized coating of oxide serves as the insulation either alone or with a thin varnish coating. Square or rectangular wires may be used, but ordinary magnet wire is round copper wire covered with cotton and an enamel. *Vitrotex* is a magnet wire coated with a resin enamel and covered with alkali-free glass fiber. It withstands temperatures up to 130°C, and the glass fibers dissipate heat rapidly. *Silotex* has a silicon resin and glass-fiber insulation and withstands temperatures up to 300°C. Various types of synthetic resins are used as insulation to give a high dielectric strength and heat and abrasion resistance. Heat resistance is usually designated by the AIEE class standards.

Magnetic

Having the capacity to be attracted by, or repelled by, other magnetized materials or fields. Commonly, metals such as iron are described as magnetic as they are strongly attracted by magnetic fields. More strictly, such metals are ferromagnetic since some other metals, termed **paramagnetic**, have the same characteristics but to a very weak extent. The remaining metals and all nonmetals are repelled by magnetic fields and are termed *diamagnetic*. “Magnetic” indicates the commonly understood form, that is, *ferromagnetic*. A material is termed magnetically hard if it is ferromagnetic and it retains most of its magnetism after the removal of the magnetizing field, termed *permanent magnetism*. If it loses its magnetism, it is termed *soft*. The magnetic properties of elements arise from their atomic structures. An atom can be considered as comprising a central nucleus around which the electrons orbit. Each electron is spinning about its own axis so it develops its individual magnetic field. However, no more than two electrons can exist at a particular energy level. Were they do exist, they are of opposite spin, so their fields cancel out, and the atoms having all their electrons paired do not independently align to produce powerful magnetic effects. These are the diamagnetic materials, and in a magnetic field, their atoms realign to oppose the external field. They carry a slightly smaller magnetic flux than would a vacuum and have a permeability of less than unity. In those elements having single electrons at particular energy levels, the unpaired electrons have magnetic moments that are not canceled, out and hence the individual atoms have magnetic moments. When exposed to an external magnetic field, these atoms realign to produce a magnetic flux greater than that in a vacuum, hence they have a permeability greater than unity, and they are attracted to the field. Elements having this characteristic to a small extent are termed paramagnetic; those having it to major extent—iron, cobalt, nickel, and gadolinium, are ferromagnetic. See also *ferrites*.

Magnetic Alignment

An alignment of the electron-optical axis of the electron microscope so that the image rotates about a point in the center of the viewing section when the current flowing through her lens is varied. See also *alignment*.

Magnetic Annealing

The annealing of steel followed by slow cooling in a powerful magnetic field to develop magnetic characteristics such as increased permeability.

Magnetic Bearing

A type of bearing in which the force that separates the relatively moving surfaces is produced by a magnetic field.

Magnetic Ceramics

Inorganic nonmetallic materials having properties associated with the phenomena of magnetism, that is, these materials can produce or conduct magnetic lines of force capable of interacting with electric fields or other magnetic fields. Magnetic ceramics form the basis for numerous devices that rely on soft or hard (permanent) magnets. The soft magnets include materials such as the *ferrites* and *garnets*, while the hard magnets include magnetoplumbites and $\gamma\text{-Fe}_2\text{O}_3$. The applications are diverse, from items such as microwave components to recording tape. They are particularly useful for high-frequency devices and can be found in numerous television and radio applications. In thin films applied to nonmagnetic substrates, these types of ceramics form the basis for magnetic bubble memories for computers.

Magnetic Circuit

The complete path followed by magnetic lines of force from pole to pole.

Magnetic Contrast

In electron microscopy, contrast that arises from the interaction of the electrons in the beam with the magnetic fields of individual magnetic domains in ferromagnetic materials. Special instrumentation is required for this type of work.

Magnetic Core

The central core of an electro magnet. It is formed from a solid piece or laminations of a magnetically soft iron or steel and is magnetic to a significant extent only while there is an electrical current in this coil surrounding it.

Magnetic Domain

The zone of material with its atoms all having the same magnetic characteristics. An individual grain will comprise multiple domains.

Magnetic Etching

The use of magnetized particles in a colloidal suspension (ferrofluid) to reveal specific features in the microstructure of fully or partially

magnetic materials. Used primarily to observe domain of magnetic materials in order to relate metallographic and domain structures to properties. See also *domain*, *magnetic*.

Magnetic Ferroelectrics

These are materials that display both magnetic order and spontaneous electric polarization. Research of these materials has enabled considerable advances to be made in understanding the interplay between magnetism and ferroelectricity. The existence of both linear and higher-order coupling terms has been confirmed, and their consequences studied. They have given rise, in particular, to a number of magnetically induced polar anomalies and have even provided an example of a ferromagnetic whose magnetic moment per unit volume is totally induced by its coupling via linear terms to a spontaneous electric dipole moment.

Most known ferromagnetic materials are metals or alloys. Ferroelectric materials, on the other hand, are nonmetals by definition because they are materials that can maintain a spontaneous electric moment per unit volume (called the polarization), which can be reversed by the application of an external electric field. It, therefore, comes as no surprise to find that there are no known room-temperature ferromagnetic ferroelectrics. In fact, there are no well-characterized materials that are known to be both strongly ferromagnetic and ferroelectric at any temperature. This is unfortunate because not only would a study of the interactions between ferromagnetism and ferroelectricity be valuable as basic research but such interplay could well give rise to important device applications.

Most antiferromagnetic materials, however, are nonmetals, so there is no apparent reason ferroelectricity and antiferromagnetism should not coexist. A study of antiferromagnetic ferroelectrics would also provide much information concerning the interplay of magnetic and ferroelectric characteristics even if the device potential were very much reduced. Somewhat unaccountably, antiferromagnetic ferroelectrics are also comparative rarities in nature.

The antimagnetic ferroelectrics BaMnF_4 , BaFeF_4 , BaNiF_4 , and BaCoF_4 and their nonmagnetic magnesium and zinc counterparts are orthorhombic and all spontaneously polar (i.e., pyroelectric) at room temperature. For all except the iron and manganese materials, which have a higher electrical conductivity than the others, the polarization has been reversed by the application of an electric field, so that they are correctly classified as ferroelectric, although their ferroelectric transition (or Curie) temperatures are in general higher than their melting points.

The importance of these magnetic ferroelectrics is the opportunity they provide to study and to separate the effects of a variety of magnetic and nonmagnetic excitations upon the ferroelectric properties and particularly upon the spontaneous polarization.

Magnetic Field

The region within which a body or current experiences magnetic force.

Magnetic Flux

The rate of flow of magnetic energy across or through a surface.

Magnetic Forming

The use of short-duration, high-intensity magnetic fields to induce deformation. The material to be shaped, which must be a conductor,

is subject to a rapidly changing magnetic field that induces, in the body of the material, large eddy currents, and associated magnetic fields. The interaction of the induced and external magnetic fields produces large forces capable of deforming the material.

Magnetic Heating

Magnetic heating is bidding for recognition as a mainstream thermal technology with the introduction of the Coreflux process. The equipment generates an intense low-frequency magnetic field throughout the cross section of magnetic and paramagnetic materials.

The process is sometimes called UMH for “uniform magnetic heating,” because it heats the entire cross section of a workpiece simultaneously. Temperature distribution is uniform; there is little or no thermal gradient from the surface to the center.

However, UMH should not be confused with low-frequency induction heating. Although both processes require magnetic fields, that is where the similarity ends. Induction heating is a surface process. The induction coil generates magnetic eddy currents that are stronger on the surface of the workpiece than at the center. This produces a skin heating effect, and conductivity carries heat into the interior of the part.

Low-frequency induction heating systems (around 60 Hz) can penetrate components to a depth of no more than 25 mm for most materials. This type of system still uses eddy currents to generate the heat—so, uniform through-heating of thicker parts is not possible.

Process Principles

UMH is based on the principle of hysteresis loss and heats without relying on thermal conductivity to transmit heat from the surface to the center. With UMH, an alternating magnetic field causes domains or crystals in the metal to align and strain in reaction to the field (in the direction of the field for ferrous metals; in the opposite direction for nonferrous metals). As field polarity is reversed, these domains realign; the lag in the process, called hysteresis, is the mechanism that creates heat. This heat has spread rapidly and uniformly through the metal component.

Process Differences

Both induction heating and UMH use coils, but in very different ways. A part to be heated by induction is placed within the loops of a single coil. The magnetic field for UMH is generated by two coils that induce magnetic fields in two cores laminated from high-permeability, low-reluctance directional steel. The cores direct magnetic flux into the workpiece, and pneumatic cylinders clamp the workpiece between the laminated cores to prevent vibration when the field is energized.

For large masses that require uniform heating to produce optimum results, UMH is a logical alternative to induction.

Generating the field for uniform magnetic heating requires less energy and equipment than induction heating and can produce a field that can be varied from 40 to 400 Hz using a standard, variable-frequency motor drive inverter. It is less costly than the power supply for induction heating.

Another advantage is that UMH has no plumbing, so the installation is simplified, and one of the other biggest advantages of this power supply is that water cooling is eliminated; only 480 VAC three-phase electric service and 90 psi shop air are needed. Also, a huge amount of induction heat is lost in water-cooling the coil. With the air-cooled coils, most of the energy flows to the workpiece.

M

UMH also has a tooling advantage. The same laminated cores can be used for a variety of parts. Induction heating, however, requires a separate coil customized for each component.

Temperatures can be maintained to an accuracy of $\pm 2^\circ\text{C}$, which is generally a tighter tolerance than most users can measure. A proportional integral derivative (PID) controller tapers the percentage output of the power supply as the workpiece reaches the required temperature, to avoid overshooting the set point. The programmable logic controller includes a touchscreen interface and multiple thermocouple inputs.

Processing

UMH is capable of heating up to 1100°C , well beyond the Curie point, at which magnetic materials lose their magnetic properties. But its benefits compared to induction heating are said to be more tangible at sub-Curie temperatures, at which induction tends to overheat part surfaces.

UMH can through-heat to 260°C – 316°C very efficiently, while induction really struggles at these low temperatures because localized surface heating is very pronounced and there is little penetration. Above the Curie point, the eddy currents of induction heating penetrate deeper into the workpiece.

Applications

UMH machines can be applied to tempering, stress relieving, and hardening of parts as well as bonding and shrink fitting and are all sound applications. UMH can also preheat billets for extrusion and semisolid forming, and dies for extrusion and forging. Sintering of powder metals and brazing are among its other capabilities.

Magnetic Irons and Steels

All magnetic materials fall into two general classes: they are either permanently or nonpermanently magnetized. The permanently magnetized materials retain their magnetization after being placed in a magnetic field and can be used as a constant source of magnetic field. On the other hand, the nonpermanently magnetized, or soft magnetic materials, retain their magnetization only while a magnetic field is applied to the material.

The basic magnetization process and hysteresis cycle are best understood in terms of the static domain theory, which is applicable under DC excitation. However, most applications of magnetic materials are for AC use. The predominant frequency commercially used in the United States is 60 cycles. For many special applications, particularly in the aircraft and military field, 400 cycles is a common frequency. The AC losses are not simple multiples of the DC hysteresis loss, for in addition to the basic magnetic losses.

Applications

The magnetic alloys used for AC applications are used in sheet form and are most often alloyed so that maximum resistivity is obtained commensurate with the induction required, ability to hot- and cold-work the material, minimum hysteresis loss, and cost.

The number of applications of magnetic materials is so large that a complete listing is not feasible. Furthermore, even for the same general application, such as a motor, many acceptable designs could be made, each requiring different quality levels of magnetic material. Therefore, no attempt will be made to evaluate all the uses for

a given alloy. However, several typical uses will be given. In some instances, very special properties of a magnetic material may be required. The most common magnetic materials with their characteristic AC and DC properties can be found in Tables M.3 and M.4, pp. 378–379, Second Edition, *Encyclopedia of Materials, Parts, and Finishes*—CRC Press (Mel Schwartz).

Tables M.3 and M.4 are designed to give the reader a ready reference source to identify the kinds of materials available and a brief resume of their most important properties. After preliminary selection, reference should be made to the detailed curves available from reputable suppliers before any design is anticipated. Many of the materials listed require special handling and annealing techniques to achieve optimum properties.

Magnetic Lens

A device for focusing an electron beam using a magnetic field.

Magnetic Materials (Hard and Soft)

These are materials exhibiting ferromagnetism. The magnetic properties of all materials make them respond in some way to a magnetic field, but most materials are diamagnetic or paramagnetic and show almost no response.

The materials that are most important to magnetic technology are ferromagnetic and ferrimagnetic materials. Their response to a field H is to create an internal contribution to the magnetic induction B proportional to H , expressed as $B = \mu H$, where μ is the permeability, varies with H for ferromagnetic materials. Ferromagnetic materials are the elements iron, cobalt, nickel, and their alloys, some manganese compounds, and some rare earths. Ferrimagnetic materials are spinels of the general composition $M\text{Fe}_2\text{O}_4$, and garnets, $M_3\text{Fe}_5\text{O}_{12}$, where M represents a metal.

Ferromagnetic materials are characterized by a Curie temperature above which thermal agitation destroys the magnetic coupling giving rise to the alignment of the elementary magnets (electron spins) of adjacent atoms in a crystal lattice. Below the Curie temperature, ferromagnetism appears spontaneously in small volumes called domains. In the absence of a magnetic field, the domain arrangement minimizes the external energy and the bulk material appears unmagnetized.

Magnetic materials are further classified as soft or hard according to the ease of magnetization. Soft materials are used in devices in which change in the magnetization during operation is desirable, sometimes rapidly, as in AC generators and transformers. Hard materials are used to supply a fixed field either to act alone, as in a magnetic separator, or to interact with others, as in loudspeakers and instruments. Both soft and hard materials are characterized by their magnetic hysteresis curve.

These two broad groups—soft magnetic materials, sometimes called electromagnets—do not retain their magnetism when removed from a magnetic field; hard magnetic materials, sometimes referred to as permanent magnets, retain their magnetism when removed from a magnetic field. Cobalt is the major element used for obtaining magnetic properties in hard magnetic alloys.

Soft Materials

These materials are characterized by their low loss and high permeability. There are a variety of alloys used with various combinations of magnetic properties, mechanical properties, and cost.

There are seven major groups of commercially important materials: iron and low-carbon steels, iron–silicon alloys, iron–aluminum–silicon alloys, nickel–iron alloys, iron–cobalt alloys, ferrites, and amorphous alloys.

The behavior of soft materials is controlled by the pinning of domain walls at heterogeneities such as grain boundaries and inclusions. Thus, the common goal in their production is to minimize such heterogeneities. In addition, eddy current loss is minimized through alloying additions that increase the electrical resistivity. Initial permeability, important in electronic transformers and inductors, is improved by minimizing all sources of magnetic anisotropy, for example, by using amorphous metallic alloys and by using zero magnetostrictive alloys. A high maximum permeability, which is necessary for motors and power transformers, is increased by the alignment of the anisotropy, for example, through development of crystal texture or magnetically induced anisotropy.

The class of alloys used in the largest volume is by far iron and 1%–3.5% silicon–iron for applications in motors and large transformers. In these applications, the cost of the material is often the dominant factor, with losses and excitation power secondary but still important. Thus, the improvement over the years in these alloys has been in developing lower losses without increases in cost.

Soft magnetic materials are iron, iron–silicon alloys, and nickel–iron alloys. Irons are widely used for their magnetic properties because of their relatively low cost. Common iron–silicon magnetic alloys contain 1%, 2%, 4%, and 5% silicon. There are about six types of nickel–irons, sometimes called permeability alloys, used in magnetic applications. For maximum magnetostriction, the two preferred nickel contents are 42% and 79%. Additions of molybdenum give higher resistivities, and additions of copper result in higher initial permeability and resistivity.

Soft magnetic ceramics, also referred to as ceramic magnets, ferromagnetic ceramics, and ferrites (soft), were originally made of an iron oxide, Fe_2O_3 , with one or more divalent oxides such as NiO , MgO , or ZnO . The mixture is calcined, ground to a fine powder, pressed to shape, and sintered. Ceramic and intermetal types of magnets have a square hysteresis loop and high resistance to demagnetization and are valued for magnets for computing machines where a high remanence is desired. A ferrite with a square loop for switching in high-speed computers contains 40% Fe_2O_3 , 40% MnO , and 20% CdO . Some intermetallic compounds, such as zirconium–zinc, ZrZn_2 , which are not magnetic at ordinary temperatures, become ferromagnetic with properties similar to ferrites at very low temperatures and are useful in computers in connection with subzero superconductors. Some compounds, however, are the reverse of this, being magnetic at ordinary temperatures and nonmagnetic below their transition temperature point. This transition temperature, or Curie point, can be arranged by the compounding to vary from subzero temperatures to above 100°C. Chromium–manganese–antimonide, $\text{Cr}_x\text{Mn}_{2-x}\text{Sb}$, is such a material. Chromium–manganese alone is ferromagnetic, but the antimonide has a transition point varying with the value of x .

Vectolite is a lightweight magnet made by molding and sintering ferric and ferrous oxides and cobalt oxide. The weight is 3.2 g/cm³. It has high coercive force and has such high electrical resistance that it may be considered as a nonconductor. *Magnadur* was made from barium carbonate and ferric oxide. *Indox* and *Ferroxdure* are similar. This type of magnet has a coercive force to 127,200 A/m, with initial force to 206,700 A/m, high electrical resistivity, high resistance to demagnetization, and light weight, with specific gravity from 4.5 to 4.9. *Ferrimag* and *Cromag* are ceramic magnets.

Strontium carbonate is superior to barium carbonate for magnets but is more costly. *Lodex* magnets are extremely fine particles of iron–cobalt in lead powder made into any desired shape by powder metallurgy.

Hard Materials

Permanent magnets, or hard magnetic materials, strongly resist demagnetization once magnetized. They are used, for example, in motors, loudspeakers, meters, and holding devices, and have coercivities H_c from several hundreds to many thousands of oersteds (10 to over 100 kA/m). The bulk of commercial permanent magnets are of the ceramic type, followed by the Alnicos and the cobalt–samarium, iron–neodymium, iron–chromium–cobalt, and elongated single-domain (ESD) types in decreasing sequence of usage. The overall quality of a permanent magnet is represented by the highest-energy product $(BH)_m$; but depending on the design considerations, high H_c , high residual induction B_r (the magnetic induction when H is reduced to zero), and reversibility of permeability may also be controlling factors.

To understand the relationship between the resistance to demagnetization, that is, the coercivity, and the metallurgical microstructure, it is necessary to understand the mechanisms of magnetization reversal. The two major mechanisms are reversal against a shape anisotropy and reversal through nucleation and growth of reverse magnetic domains against crystal anisotropy. The Alnicos, the iron–chromium–cobalt alloys, and the ESD *Lodex* alloys are examples of materials of the shape anisotropy structure, whereas barium ferrites, the cobalt–samarium alloys, and the iron–neodymium–boron alloys are examples of the crystal anisotropy-controlled materials.

Neodymium–iron–boron is a powerful magnetic material that works best at room temperature. It begins losing its properties at higher temperatures, and at 312°C it loses its magnetism completely.

The use of magnets in a Stirling engine to power deep space probes has been investigated. Stirling engines have a sealed cylinder in which hot gases move two pistons back and forth. By placing magnets on the ends of the pistons, and surrounding the cylinder with wire coils, the magnets would induce a current flow.

Research is being conducted whereby a magnetic material that would work at elevated temperature is being produced in particles that each have two different compositions—one at the outer edge to resist demagnetization, and the other at the core to retain magnetic power at higher temperatures. The “functionally graded” material would essentially have the outside material protecting the inside material.

The new magnets would be attractive for a variety of applications on Earth as well—cars, electronics, computers, and power tools.

Magnet steels, now largely obsolete, include plain high-carbon (0.65% or 1%) steels or high-carbon (0.7%–1%) compositions containing 3.5% chromium–chromium magnet steels; 0.5% chromium and 6% tungsten–tungsten magnet steel; or chromium, tungsten, and substantial cobalt (17% or 36%)–cobalt magnet steels. They were largely replaced by ternary alloys of iron, cobalt, and molybdenum, or tungsten. *Comol* has 17% molybdenum, 20% cobalt, and 71% iron. *Indalloy* and *Remalloy* have similar compositions: about 20% molybdenum, 12% cobalt, and 68% iron. *Chromindur* has 28% chromium, 15% cobalt, and the remainder iron, with small amounts of other elements that give it improved strength and magnetic properties. In contrast to *Indalloy* and *Remalloy*, which must be processed at temperatures as high as 1250°C, *Chromindur* can be cold-formed.

M

Some cobalt magnet steels contain 1.5%–3% chromium, 3%–5% tungsten, and 0.50%–0.80% carbon, with high cobalt. *Alfer* magnet alloys, first developed in Japan to save cobalt, were iron–aluminum alloys. *MK* alloy had 25% nickel, 12% aluminum, and the balance iron, close to the formula Fe_2NiAl .

Cunife is a nickel–cobalt–copper alloy that can be cast, rolled, and machined. It is not magnetically directional like the tungsten magnets, and thus gives flexibility in design. The electric conductivity is 7.1% that of copper, and it has good coercive force. *Cunife 1* contains 50% copper, 21% nickel, and 29% cobalt. *Cunife 2*, with 60% copper, 20% nickel, and 20% iron, is more malleable. This alloy, heat-treated at 593°C, is used in wire form for permanent magnets for miniature apparatus. It has a coercive force of 39,750 A/m. *Hipernom* is a high-permeability nickel–molybdenum magnet alloy containing 79% nickel, 4% molybdenum, and the balance iron. It has a Curie temperature of 460°C and is used for relays, amplifiers, and transformers.

In the Alnico alloys, a precipitation hardening occurs with AlNi crystals dissolved in the metal and aligned in the direction of magnetization to give greater coercive force. This type of magnet is usually magnetized after setting in place. Alnico 1 contains 21% nickel, 12% aluminum, 5% cobalt, 3% copper, and the balance iron. The alloy is cast to shape, is hard and brittle, and cannot be machined. The coercive force is 31,800 A/m. Alnico 2, a cast alloy with 19% nickel, 12.5% cobalt, 10% aluminum, 3% copper, and the balance iron, has a coercive force of 44,520 A/m. The cast alloys have higher magnetic properties, but the sintered alloys are fine-grained and stronger. Alnico 4 contains 12% aluminum, 27% nickel, 5% cobalt, and the balance iron; it has a coercive force of 55,650 A/m, or 10 times that of a plain tungsten magnet steel. Alnico 8 has 35% cobalt, 34% iron, 15% nickel, 7% aluminum, 5% titanium, and 4% copper. The coercive force is 115,275 A/m. It has a hardness of Rockwell C 59. The magnets are cast to shape and finished by grinding. *Hyflux Alnico 9*, of the same coercive force, has an energy product of 75,620 T A/m. The magnets of this material, made by Indiana General Corp., are cylinders, rectangles, and prisms, usually magnetized and oriented in place. The *Alnicus* magnets are Alnico-type alloys with the grain structure oriented by directional solidification in the casting, which increases the maximum energy output. *Ticonal*, *Alcomax*, and *Hycomax* are Alnico-type magnet alloys produced in Europe.

Cobalt–platinum, as an intermetallic rather than an alloy, has a coercive force above 341,850 A/m and a residual induction of 0.645 T. It contains 76.8% by weight of platinum and is expensive, but is used for tiny magnets for electric wristwatches and instruments. *Placovar* is a similar alloy that retains 90% of its magnetization flux up to 343°C. It is used for miniature relays and focusing magnets. *Ultramag* is a platinum–cobalt magnet material with a coercive force of 381,600 A/m. The Curie temperature is about 500°C, and it has only slight loss of magnetism at 350°C, whereas cobalt–chromium magnets lose their magnetism above 150°C. The material is easily machined. *Alloy 1751* is a cobalt–platinum intermetallic with a coercive force of 341,850 A/m, or of 540,600 A/m in single-crystal form. The metal is not brittle and can be worked easily. It is used for the motor and index magnets of electric watches.

Ceramic permanent magnets are compounds of iron oxide with oxides of other elements. The most used are barium ferrite, oriented barium ferrite, and strontium ferrite. Yttrium–iron garnets (YIG) and yttrium–aluminum garnets (YAG) are used for microwave applications.

Flexible magnets are made with magnetic powder bonded to tape or impregnated in plastic or rubber in sheets, strip, or forms. Magnetic tape for recorders may be made by coating a strong,

durable plastic tape, such as a polyester, with a magnetic ferrite powder. For high-duty service such as for spacecraft, the tape may be of stainless steel. For recording heads, the ferrite crystals must be hard and wear resistant.

Ferrocube is manganese zinc. The tiny crystals or compacted with a ceramic bond for pole pieces for recorders. *Plastiform* is a barium ferrite bonded with rubber in sheets and strips. *Magnyl* is a vinyl resin tape with the fine magnetic powder only on one side. It is used for door seals and display devices.

Rare earth magnetic materials, used for permanent magnets and computers and signaling devices, have coercive forces up to 10 times that of ordinary magnets. They are of several types. Rare earth–cobalt magnets are made by compacting and extruding the powders with a binder of plastic or soft metal into small precision shapes. They have high permanency. Samarium–cobalt and cesium–cobalt magnets are cast from vacuum melts and are chemical compounds, SmCo_5 and CeCo_5 . These magnets have intrinsic coercive forces up to 2.2 million A/m. The magneto optic magnets for memory systems and components are made in thin wafers, often no more than a spot in size. These are ferromagnetic ceramics of europium–chalcogenides. Spot-size magnets of europium oxide only 4 μm in diameter perform reading and writing operations efficiently. Films of this ceramic less than a wavelength in thickness are used as memory storage mediums.

Magnetic fluids consist of solid magnetic particles in a carrier fluid. When a magnetic field is applied, the ultramicroscopic iron oxide particles become instantly oriented. When the field is removed, the particles demagnetize within microseconds. Typical carrier fluids are water, hydrocarbons, fluorocarbons, diesters, organometallics, and polyphenylene ethers. Magnetic fluids can be specially formulated for specific applications such as damping, sealing, and lubrication.

Magnetic Pole

The area on a magnetized part at which the magnetic field leaves or enters the part. It is a point of maximum attraction in a magnet.

Magnetic Quenchometer Test

Method used to test heat extraction rates of various quenchants. The test works by utilizing the change in magnetic properties of metals at the Curie point—the temperature above which metals lose their magnetism. See also *Curie temperature*.

Magnetic Resonance

A phenomenon in which the magnetic spin systems of certain atoms absorb electromagnetic energy at specific (resonant) natural frequencies of the system.

Magnetic Resonance Imaging (MRI)

A technique in which an object placed in a specially varying magnetic field is subjected to a pulse of radiofrequency radiation, and the resulting nuclear magnetic resonance spectra are combined to give cross-sectional images.

Magnetic Seal

A seal that uses magnetic material, instead of springs or bellows, to provide the closing force.

Magnetic Separator

A device used to separate magnetic from less magnetic or nonmagnetic materials. The crushed material is conveyed on a belt past a magnet.

Magnetic Shielding

In electron microscopy, shielding for the purpose of preventing extraneous magnetic fields from affecting the electron beam in the microscope.

Magnetic Writing

In magnetic-particle inspection, a *false indication* caused by contact between a magnetized part and another piece of magnetic material.

Magnetically Hard Alloy

A ferromagnetic alloy capable of being magnetized permanently because of its ability to retain induced magnetization and magnetic poles after removal of externally applied fields; an alloy with high coercive force. The name is based on the fact that the quality of the early permanent magnets was related to their hardness. See also *permanent magnet materials*.

Magnetically Soft Alloy

A ferromagnetic alloy that becomes magnetized readily upon application of the field and that returns to practically a nonmagnetic condition when the field is removed; an alloy with the properties of high magnetic permeability, low coercive force, and low magnetic hysteresis loss. See also *soft magnetic materials*.

Magnetic-Analysis Inspection

A nondestructive method of inspection to determine the existence of variations in magnetic flux in ferromagnetic materials of constant cross section, such as might be caused by discontinuities and variations in hardness. The variations are usually indicated by a change in pattern on an oscilloscope screen.

Magnetic-Particle Inspection

A nondestructive method of inspection for determining the existence and extent of surface cracks and similar imperfections in ferromagnetic materials.

The use of magnetic particles to detect surface defects in iron and steel. The fine particles, as a dry powder or suspended in fluid, are applied to the surface under test, and a magnetic field is imposed by magnets or electrical coils. Any defect aligned across the lines of magnetic force effectively forms a pair of magnets that attract the particles hence revealing the location of the defect. Prior to application of the particles, it is, to apply a quick drying white coating, referred to as a developer, to improve contrast.

Magnetic-Shielding Metals

The materials that fall under this category are used in airport environments, which deal with what is known in the industry as ELF (extremely low frequency) radiation interference to ticketing computer terminals caused by the close proximity of building utility electrical faults as well as to main switchgear rooms.

Another application is in the production of handheld electronic equipment with and without radio cards.

Material Types

MuShield works primarily with an 80% nickel alloy. The alloy with such trade names as *HyMu 80*, *Permalloy*, and *MuMetal* shields from low-frequency electromagnetic interference. For high-frequency shielding, refer to fabricators that work with copper, aluminum, and other conductive materials.

The term "B-40" is an arbitrary starting point for high-permeability alloys because it is a good average value of the flux density induced within a piece of high-permeability material.

It has also been found that time-varying (AC) magnetic fields need to be attenuated below 7 mG for most monitor applications. Also, larger monitors are more sensitive to EMI.

Magnetite Black

Magnetic iron oxide, Fe_3O_4 , in contrast to rust, magnetite, can form a protective coating. For example, in high-temperature water of good quality, it forms on the surface of steels being hot worked, in which case it is commonly termed *mill scale*.

Magnetizing Force

A force field, resulting from the flow of electric currents or from magnetized bodies, that produces magnetic induction.

Magnetoelasticity

Less common term for magnetostriction.

Magnetohydrodynamic Lubrication

Hydrodynamic lubrication in which a significant force contribution arises from electromagnetic interaction. Magnetohydrodynamic bearings have been proposed for very high-temperature operation, for example, in liquid sodium.

Magnetometer

An instrument for measuring the magnitude and sometimes also the direction of a magnetic field, such as the Earth's magnetic field. See also *torque-coil magnetometer*.

Magnetron

A unit of magnetic moment used for atomic, molecular, or nuclear magnets. The Bohr magneton (μ_B), which has the value of the classical magnetic moment of the electron, can theoretically be calculated as

$$\mu_B = \frac{eh}{2mc} = 9.2731 \times 10^{-20} \text{ erg/G}$$

where

e and m are the electronic charge and mass, respectively

h is Planck's constant divided by 2π

c is the velocity of light

See also *Planck's constant*.

M

Magnetostriction

The reversible dimensional change of a material due to magnetization. The change may be expansion or contraction, volumetric (Barret effect), or linear (Joule effect).

Magnetostriction occurs where in a position sensor, a pulse is induced in a magnetostrictive waveguide by the momentary interaction of two magnetic fields: one from a magnet passing along the outside of the sensor tube, and the other field from a current pulse launched along a waveguide within the tube. The interaction produces a strain pulse (twisting the waveguide) that travels at sonic speeds down the waveguide until detected at the sensor head. Measuring the elapsed time between the launching of the electronic pulse and the arrival of the strain pulse, or pulses, precisely determines the position of one, or more, magnets.

Such noncontact position sensing produces no wear in the sensing elements, cutting maintenance and extending sensor life. The encapsulated waveguide and electronics also provide durability in severe environments. And, modularity gives mounting flexibility and easy integration.

Magnetostrictive Cavitation Test Device

A vibratory cavitation test device driven by a magnetostrictive transducer.

Magnification

In metallography, the ratio of the image diameter to the object diameter. It approximates to the product of the magnifications of the eyepiece and the objective lenses of the microscope.

Magnolia Metal

A cheap white metal bearing metal suitable only for light duty but retaining its properties to a relatively high temperature. Typically 80% lead, 15% antimony, and 5% tin.

Magnox Alloys

Nuclear fuel canning alloys based primarily on magnesium with small amounts of elements such as aluminum and beryllium added to reduce flammability, limit grain size, and enhance resistance to high-temperature oxidation in carbon dioxide, the cooling medium in magnox reactors.

Magnox Reactors

Nuclear reactors of a design cooled by carbon dioxide and having the fuel canned in magnox alloy.

Main Bearing

A bearing supporting the main power-transmitting shaft.

Major Segregation

See *segregation*.

Male

A term used to identify the item in an assembly that fits inside another. It may be regarded as not “politically correct.”

Malleability

The characteristic of metals that permits *plastic deformation* in compression without fracture. See also *ductility*. The capacity of a metal to be deformed by predominately compressive loads in processes such as rolling, forging, or beating.

Malleabilizing

Annealing *white iron* in such a way that some or all of the combined carbon is transformed into graphite or, in some cases, so that part of the carbon is removed completely.

Malleable Iron

A cast iron made by prolonged annealing of *white iron* in which decarburization, graphitization, or both take place to eliminate some or all of the cementite. The graphite is in the form of temper carbon. If decarburization is the predominant reaction, the product will exhibit a light fracture surface; hence, whiteheart malleable. Otherwise, the fracture surface will be dark; hence, blackheart malleable. Only the blackheart malleable is produced in the United States. Ferritic malleable has a predominately ferritic matrix; pearlitic malleable may contain pearlite, spheroidite, or tempered martensite, depending on heat treatment and desired hardness. Small amounts of chromium (0.01%–0.03%), boron (0.0020%), copper (~1.0%), nickel (0.5%–0.8%), and molybdenum (0.35%–0.5%) are also sometimes present.

Malleable Irons

The malleable irons are a family of cast alloys—consisting primarily of iron, carbon, and silicon—which are cast as hard, brittle white iron and then rendered tough and ductile through a controlled heat conversion process. Because of their unique metallurgical structure, they possess a wide range of desirable engineering properties including strength, toughness, ductility, resistance to corrosion, machinability, and castability.

Three principal types of malleable iron are in wide use in this country; ferritic, pearlitic, and alloy malleable iron. A fourth type, called cupola malleable because of the method of manufacture, is also produced but only in small tonnages. Most important from the standpoint of production volume and use is standard malleable iron, which has a ferrite matrix. Pearlitic malleable, which, as the name implies, has a pearlitic matrix, is being produced in ever-increasing quantities. Alloy malleable iron is basically a specialty type iron with higher strength and corrosion resistance, finding primary use in railroad parts.

By far the largest tonnage of malleable castings normally is consumed by the automotive industry. The railroad, agricultural implement, electrical line hardware, pipe fittings, and detachable chain industries, and most other basic industries use standard and pearlitic malleable castings.

Advantages

Important attributes of malleable iron can be summarized as follows:

1. Malleable iron can be produced with a high yield strength, which is a static mechanical property upon which most mechanical design is based.
2. Ferritic and pearlitic malleable irons have a high ratio of yield strength to tensile strength. This means that the engineer can design to high applied strength values in service

for materials of construction, concomitant with good machinability, and low production cost for the final part.

3. Pearlitic malleable irons can be produced to a wide range of mechanical properties through carefully controlled heat treatments.
4. Malleable irons have a high modulus of elasticity and a low coefficient of thermal expansion, compared with the nonferrous metals.
5. Malleable and pearlitic malleable irons exhibit a low nil ductility transition temperature for brittle fracture.
6. Compared with steel, malleable and pearlitic malleable irons have considerably better damping capacity, which makes operation of moving components less prone to noise because of resonant vibration.
7. Pearlitic malleable irons exhibit good wear resistance and can be selectively hardened by flame, induction, or the carbonitriding process.
8. Pearlitic malleable irons will take a high-quality finish. Honed surfaces with 2–3 $\mu\text{in.}$ finish and hardness values of 197–207 Bhn have been reported.
9. The uniformity of properties from surface to center is excellent, particularly in oil-quenched and tempered pearlitic malleable iron.
10. All malleable irons are substantially free from residual stresses as a result of long heat treatments at high temperatures.
11. Pearlitic malleable iron provides the properties of medium to high carbon steel coupled with a machinability rating unequaled for a material of similar hardness.

With respect to mechanical properties, minimum specification values are generally exceeded by a comfortable margin in the better-controlled malleable foundries.

Brinell hardness of ferritic malleable irons varies from about 110 to 145. Pearlitic malleable and alloyed malleable iron grades have higher values, ranging usually between 160 and 280 Bhn. Both hardness and tensile strength increase with combined carbon content.

Since the final properties of malleable iron castings are the result of thermal treatments, section thickness has no appreciable effect on strength. Therefore, mechanical properties will be essentially the same throughout the entire cross section.

Manufacture

The manufacture of malleable iron castings is fundamentally a two-phase operation. Phase 1 consists of producing the white iron castings, and the second phase involves the controlled heat treatment of these castings to obtain the desired finished product.

Structurally, malleable iron castings consist essentially of carbon-free iron (ferrite) and uniformly dispersed nodules of temper carbon. This combination of soft, ductile ferrite and nodular temper carbon accounts for the desirable mechanical properties of malleable iron. In pearlitic malleable iron, the matrix is essentially pearlitic, resembling that of a medium-carbon steel.

Properties

Effect of Temperature

Studies of the behavior of ferritic malleable iron at both high and lower temperatures demonstrate, in general, that this material is well suited to applications in a temperature range from -51°C to 649°C .

Low-temperature investigations have been concerned primarily with impact resistance and notch sensitivity; high-temperature

studies have focused principally on tensile strength, yield point, elongation, stress rupture, and creep behavior.

Results of research have indicated a high level of performance at elevated temperatures, equal or superior to other ferritic materials for which data are available, particularly at 427°C . Strength at 538°C is adequate for many applications, and strength is retained even at 649°C . No evidence was found in any of the investigations of changes in structure or performance during the test periods, which extended from 1 to over 2000 h.

Surface Hardness

Many structural parts require high surface hardness backed up by a strong, tough core. In steel components, this can be accomplished by carburizing or nitriding after machining, followed by a suitable heat treatment. In pearlitic malleable iron, the combined carbon content is adequate for production of high surface hardnesses through quenching after either induction or flame heating. Many parts are preferentially hardened on wearing surfaces.

Mandrel (Metals)

- (1) A blunt-ended tool or rod used to retain the cavity in a hollow metal product during working.
- (2) A metal bar around which other metal may be cast, bent, formed, or shaped.
- (3) A shaft or bar for holding work to be machined.
- (4) A form, such as a mold or matrix, used as a cathode in electroforming.

Mandrel (Plastics and Reinforced Plastics)

- (1) In blow molding of thermoplastics, part of the tooling that forms the inside of the container neck through which air is forced to form the hot parison to the shape of the mold.
- (2) In extrusion of thermoplastics, the solid, cylindrical part of the die that forms tubing or pipe.
- (3) In filament winding of reinforced plastic, the form (usually cylindrical) around which the filaments are wound.

Mandrel Forging

The process of rolling or forging a hollow blank over a mandrel to produce a weldless, seamless ring or tube. See also *radial forging*.

Manganese and Alloys

A metallic element, symbol Mn, manganese, is found in the minerals manganite and pyrolusite and with most iron ores and traces in most rocks. Manganese has a silvery-white color with purplish shades.

It is brittle but hard enough to scratch glass. The specific gravity is 7.42, melting point 1245°C , and weight is 7418 kg/m^3 . It decomposes in water slowly. It is not used alone as a construction metal. The electrical resistivity is 100 times that of copper or 3 times that of 18-8 stainless steel. It also has a damping capacity 25 times that of steel and can be used to reduce the residence of other metals.

It is the 12th most abundant element in the Earth's crust (approximately 0.1%) and occurs naturally in several forms, primarily as a silicate (MnSiO_3) but also as the carbonate (MnCO_3) in a variety of oxides, including pyrolusite (MnO_2) and hausmannite (Mn_3O_4). Pyrolusite is the most common and has been used in glassmaking since the time of the pharaohs in Egypt. Weathering of land deposits has led to large amounts of the oxide being washed out to sea, where they have aggregated into the so-called manganese nodules containing 15%–30% manganese. Vast deposits, estimated at over

10^{12} metric tons, have been detected on the seabed, and a further 10^7 metric tons is deposited every year. The nodules also contain smaller amounts of the oxides of other metals such as iron, cobalt, nickel, and copper. The economic importance of the nodules as a source of these important metals is enormous.

Uses

All steels contain some manganese, the major advantage being an increase in hardness, although it also serves as a scavenger of oxygen and sulfur impurities that would induce defects and consequent brittleness in the steel. The manganese ore is first converted to a metallic alloy with iron known as ferromanganese.

Ferromanganese has a significantly lower melting point than pure manganese and is therefore more readily dissolved by molten iron for steel production. The demand for manganese by the steel industry is so great that about 95% of mined manganese ores are converted to ferromanganese.

In addition to its importance to the steel industry, manganese has a number of other industrial uses. Manganese dioxide (MnO_2) is employed in the manufacture of dry-cell batteries, most commonly of the carbon–zinc Leclanché type. It acts to suppress undesirable formation of hydrogen gas at the carbon (positive) electrode. Only very high-quality manganese dioxide ore can be used directly in these batteries; consequently, increasing use is being made of synthetic manganese dioxide obtained by the electrolysis of manganese sulfate (MnSO_4) solutions. Manganese dioxide is also used in the brick industry to provide a range of red-to-brown and gray tints. Its venerable use in glassmaking has been mentioned; its role is to neutralize the effects of iron impurities that would impart a greenish tinge to the glass. The good oxidizing properties of manganese dioxide also make it useful for the oxidation of aniline to quinone, important as a photographic developer and also in the production of paints and dyes. Manganese even has some use in the electronics industry, where manganese dioxide, either natural or synthetic, is employed to produce manganese compounds possessing high electrical resistivity; among other applications, these are utilized as components in every television set.

Manganese metal has very high sound-absorbing properties, and copper–manganese alloys with high percentages of manganese are used as sound-damping alloys for thrust collars for jackhammers and other power tools.

Alloys

A manganese alloy with 72% manganese, 18% copper, and 10% nickel is noted for its high coefficient of thermal expansion, electrical resistivity, strength, and vibration dampening. It is used for rheostat resistors and electrically heated expansion elements.

Manganese–aluminum is a hardener alloy employed for making additions of manganese to aluminum alloys. Manganese lowers the thermal conductivity of aluminum but increases strength. Manganese up to 1.2% is used in aluminum alloys when strength and stiffness are required. One manganese–aluminum contains 25% manganese and 75% aluminum. Manganese–boron is used for deoxidizing and hardening bronzes. It contains 20%–25% boron, with small amounts of iron, silicon, and aluminum. For deoxidizing and hardening bronzes, nickel bronze, and copper–nickel alloys, manganese copper, or copper manganese, may be used. The alloys used contain 25%–30% manganese and the balance copper. The best grades of manganese copper are made from metallic manganese and are free from iron. For nickel bronzes and nickel alloys, the manganese copper must be free of both iron and carbon, but grades

containing up to 5% iron can be used for manganese bronze. Grades made from ferromanganese contain iron.

Manganese bronze is wrought as well as cast alloys of copper and zinc mainly, with lesser amounts of iron, aluminum, silicon, tin, and lead. The two standard alloys, C67000 (2.5%–5.0% manganese) and C67500 (0.05%–0.50% manganese), were formally designated manganese bronze B and A, respectively. Manganese bronze cast alloys constitute the C86100–C86800 series, some of which also may contain as much as 5% manganese. Some manganese bronzes were formally designated high-strength yellow bronzes and leaded high-strength yellow bronzes.

C67500, which contains 58.5% copper, 39% zinc, 1.4% iron, 1% tin, and 0.1% manganese, has an ultimate tensile strength of 448 MPa, a tensile yield strength of 207 MPa, and a tensile elongation of 33% in the annealed condition. The alloy is weldable; has good brazing and soldering characteristics; and has good resistance to corrosion in rural, industrial, and marine atmospheres. Available in rod and shapes, it is used in pumps, clutches, and valves. Most of the cast alloys are castable by various methods, with C86200 the most versatile in this respect. As sand cast, the alloys provide typical ultimate tensile strength ranging from 448 to 793 MPa, and they are rather ductile as indicated by tensile elongations of 15%–30%. The alloys are not hardenable by heat treatment; weldability, including brazing and soldering, is generally poor or fair; and their machinability is 8%–65% that of free-cutting brass, with C86400 and C86700 the best in this respect.

Manganese Brass

A term with various interpretations, it usually indicates a brass based on 60% copper and 40% zinc with additions of about 1.5% manganese and often a percent or so of iron and aluminum. A better term for this alloy is *High-Tensile Brass*.

Manganese Dioxide

Manganese dioxide (MnO_2) is soluble in water and nitric acid and also in hydrochloric acid. It occurs in nature as the blue-black mineral pyrolusite.

In glass, manganese dioxide is used as a colorant and decolorizer. As a coloring oxide in lead potash and glasses, manganese produces an amethyst color, while in soda glass a reddish-violet is produced. Manganese suitable for such purposes should contain at least 85% MnO_2 and not more than 1% iron oxide.

The major use of manganese oxides is an ore of manganese for the manufacturing of steel; manganese serves to increase the hardness and decrease the brittleness of steel. Another important use of manganese oxides is as the cathode material of common zinc/carbon and alkaline batteries (such as flashlight batteries).

Manganese Nodules

These are concentrations of manganese and iron oxides found on the floors of many oceans. The complex growth histories of manganese nodules are revealed by the texture of module interiors.

Nodules from certain regions are significantly enriched in nickel, copper, cobalt, zinc, molybdenum, and other elements so as to make them important reserves for the strategic metals. Modern oceanographic surveys have delineated areas of the world's seafloors where nodule abundances and metal concentrations are highest.

Although mangiferous nodules and crusts have been sampled or observed on most seafloors, attention has been focused on the nickel–copper-rich nodules (2–3 wt.%) from the northern equatorial

Pacific belt stretching from Southeast Hawaii to Baja California, as well as the high-cobalt nodules and crusts from seamounts in the Central Pacific. Manganese nodules from the Atlantic Ocean and from higher latitudes in the Pacific Ocean have significantly lower concentrations of the minor strategic metals. Surveys of the Indian Ocean have revealed metal-enrichment trends comparable to those found in the Pacific Ocean nodules; high nickel–cobalt–copper-bearing nodules are found near the Equator. The ferromanganese nodules and crusts associated with submarine hydrothermal deposits have extremely low concentrations of nickel–cobalt–copper.

Chemistry

Marine manganese nodules are usually classified by mode of formation into hydrogenetic, diagenetic, and hydrothermal types. A fourth, mixed type also exists. Hydrogenetic nodules form by direct precipitation of manganese–iron oxide phases onto an existing nucleus at the sediment–water interface, diagenetic nodules are believed to be biologically driven, and hydrothermal nodules form by submarine hydrothermal activity. Hydrothermal nodules are rarely reported; in submarine hydrothermal environments, manganese–iron oxides occur mainly as crusts. Cobalt is the only strategic metal reported in hydrogenetic nodules that have relatively low manganese/iron ratios. Nodules with high nickel, cobalt, and copper contents are diagenetic and have relatively high manganese/iron ratios.

Manganese Steels

All commercial steels contain some manganese that has been introduced in the process of the oxidizing and the sulfurizing with ferromanganese, but the name was originally applied to steels containing from 10% to 15% manganese. Steels with from 1.0% to 1.5% manganese are known as carbon–manganese steel, pearlitic manganese steel, or intermediate manganese steel. Medium manganese steels, with manganese from 2% to 9% are brittle and are not ordinarily used, but steels with 1% to 2% manganese and with or without small amounts of chromium or molybdenum are used for air-hardening and oil-hardening cold-work tool steels. The original Hadfield manganese steel made in 1883 contained 10%–14.5% manganese and 1% carbon.

Manganese increases the hardness and tensile strength of steel. In the absence of carbon, manganese up to 1.5% has only slight influence on iron; as the carbon content increases, the effect intensifies.

High-manganese steels are not commercially machinable with ordinary tools, but can be cut and drilled with tungsten carbide and high-speed steel tools. The austenitic steels, with about 12% manganese, are exceedingly abrasion resistant and harden under the action of tools. They are nonmagnetic.

High-manganese steels are brittle when cast and must be heat-treated. For castings of thin sections or irregular shapes where the drastic water quenching might cause distortion, nickel of 5% may be added. The manganese–nickel steels have approximately the same characteristics as the straight manganese steels.

The manganese steels used for dipper teeth, tractor shoes, and wear-resistant castings contained 10%–14% manganese, 1%–1.4% carbon, and 0.30%–1% silicon. The tensile strength is up to 861 MPa, elongation 45%–55%, weight is 7916 kg/m³, and a Brinell hardness, when heat-treated, of 185–200.

A manganese–aluminum steel, has 30% manganese, 9% aluminum, 1% silicon, and 1% carbon. Its tensile strength is 840 MPa with the elongation of 18%, but it work-hardens rapidly, and when cold-rolled and heat-aged the tensile strength is 2068 MPa with a yield strength of 1999 MPa. This alloy forms a special type of stainless steel, with high resistance to oxidation and sulfur gases to 760°C.

Tank car steel M-128 is a manganese–vanadium steel with 0.25% carbon, up to 1.5% manganese, and 0.02% or more vanadium. It has a minimum tensile strength of 558 MPa with the elongation of 18%. This type of steel with up to 1.75% manganese is used for forgings.

Manganese Sulfide

A very common nonmetallic inclusion in steel.

Manifold

A pipe or other vessel with multiple inlet and/or outlet connections.

Manipulator

A mechanical device for handling an ingot or billet during forging.

Man-Made (Synthetic) Diamond

A manufactured diamond, darker, blockier, and considered to be more friable than most natural diamonds.

Mannesmann Process

A process for piercing tube billets in making seamless tubing. The billet is rotated between two heavy rolls mounted at an angle and is forced over a fixed mandrel. See *tube making*.

Manson–Haferd Relationship

An empirical method for extrapolating creep data based on a linear relationship between the reciprocal of the absolute temperature and the logarithm (base 10) of the time to rupture.

Manual Metal(lic) Arc Welding (MMA)

Metal arc welding in which the consumable electrode rod, installed in a suitable holder, is manipulated by the operator during the welding operation.

Manual Welding

Welding in which the operator holds key items of the equipment such as the welding torch or the electrode holder and, in addition, controls key parameters such as welding current or gas flame, and the entire welding operation is performed and controlled by hand.

Manufactured Unit

A quantity of finished adhesive or finished adhesively bonded component, processed at one time. The manufactured unit may be a bunch or a part thereof.

Maraging

A hardening process applicable to a precipitation-hardening treatment applied to a special group of iron-base alloys to precipitate one or more intermetallic compounds in a matrix of essentially carbon-free martensite. See also *maraging steels*.

The term is derived from “martensite” and “age hardening.” Such steels, on cooling from the austenitic region, that is, about 800°C,

M

developed a very low-carbon martensite that is softer and tougher than that formed in conventional steels. However, on heating to about 480°C, the highly alloyed martensite can undergo a precipitation hardening process as intermetallic particles precipitate. This produces a steel combining very high strength with good fracture toughness. The term was first used for a range of steels based on about 18% nickel, with typically, about 9% cobalt, 5% molybdenum, 0.6% titanium, and 0.1% aluminum but is now used at other alloys ranges offering the same characteristics.

Maraging Steels

The maraging steels develop unique combinations of properties that have not been obtained in conventional low-alloy steels. Some of these properties are (1) useful yield strengths to and above 2040 MPa, (2) high toughness and impact energy even at the 2040 MPa yield strength level, (3) low nil ductility temperature (NDT), (4) exceptional stress-corrosion resistance, (5) through hardening without quenching, (6) simple heat treatment, (7) good formability without prolonged softening treatments, (8) good machinability, (9) low distortion during maraging after forming or machining, (10) good weldability, and (11) freedom from decarburization problems.

The maraging steels are a family of low carbon, high-alloy steels typically containing 12%–18% nickel, 3%–5% molybdenum, 0%–12% cobalt, 0.2%–1.6% titanium, and 0.1%–0.3% aluminum (one cobalt-free grade also contains 5% chromium). They are noted for their high strength and toughness, simple heat treatment, dimensional stability during heat treating, good machinability, and excellent weldability. The term *maraging* refers to the martensitic structure that forms during heat treatment, which is a precipitation-hardening, or aging, treatment usually at 482°C. The 18% nickel steels, the most well known, are produced in four grades to provide tensile yield strength of 1379, 1724, 2069, or 2413 MPa. Although the 18% nickel steels were originally developed for aerospace applications primarily, they also are now used for die-casting dies, cold-forming dies, and molds for forming plastics.

The 9% nickel and 4% cobalt alloys were designed to provide high strength and toughness at room temperature as well as at moderately elevated temperatures—to about 427°C. Weldability and fracture toughness are good, but the alloys are susceptible to hydrogen embrittlement. The steels are used in airframes, gears, and large aircraft parts.

Marble

Marble is a term applied commercially to any limestone or dolomite taking polish. Marble is a compact crystalline limestone used for ornamental building, for large slabs for electric power panels, and for ornaments and statuary. In the broad sense, marble includes any limestone they can be polished, including breccia, onyx, and others. Pure limestone would naturally be white, but marble is usually streaked and variegated in many colors. Carrara marble, from Italy, is a famous white marble, being of delicate texture, very white, and hard. In the United States, the marbles of Vermont are noted and occur in white, gray, light green, dark green, red, black, and mottled.

Marforming Process

A *rubber-pad forming* process developed to form wrinkle-free shrink flanges and deep-drawn shells. It differs from the *Guerin process* in that the sheet metal blank is clamped between the rubber pad and the blankholder before forming begins.

Margin

The cylindrical portion of the *land* of a drill that is not cut away to provide clearance.

Marquenching

See *martempering*.

Martempering

(1) A hardening procedure in which an austenitized ferrous material is quenched into an appropriate medium at a temperature just above the martensite start temperature of the material, held in the medium until the temperature is uniform throughout, although not long enough for bainite to form, then cooled in air. The treatment is frequently followed by tempering. (2) When the process is applied to carburized material, the controlling martensite start temperature is that of the case. This variation of the process is frequently called *marquenching*. (3) In martempering, the part is held at the martensite start temperature for a limited time and then further cooling, which can be at a relatively slow rate, causes transformation to martensite. The initial fast cooling suppresses the normal pearlite transformation, and the hold at the intermediate temperature allows temperature gradients to even out, thereby reducing residual stresses. The virtual absence of residual stress and the relatively slow final cooling minimizes the risk of cracking. Austempering is similar except that it allows transformation to occur at the hold temperature, thereby forming a bainite structure. See *steel* and *isothermal transformation diagram*.

Martensite

A generic term for microstructures formed by diffusionless phase transformation in which the parent and product phases have a specific crystallographic relationship. Martensite is characterized by an acicular pattern in the microstructure in both ferrous and non-ferrous alloys. In alloys where the solute atoms occupy interstitial positions in the martensitic lattice (such as carbon in iron), the structure is hard and highly strained; but where the solute atoms occupy substitutional positions (such as nickel in iron), the martensite is soft and ductile. The amount of high-temperature phase that transforms to martensite on cooling depends to a large extent on the lowest temperature attained, there being a rather distinct beginning temperature (M_s) and a temperature at which the transformation is essentially complete (M_f). See also *lath martensite*, *plate martensite*, and *tempered martensite*.

The structure formed in steels by a shear mechanism, rather than a diffusion process, when the steel is cooled, from the austenitic range, faster than the critical rate. The fast cooling retains the carbon as a supersaturated solid solution so the face centered cubic ferrite structure cannot form. Instead, the austenite transforms by shear to a body-centered tetragonal structure that, under the microscope has an acicular, that is, needle-shaped, appearance. See *steel*. The term is used for similar crystallographic forms in other alloys.

Martensitic

A platelike constituent having an appearance and a mechanism of formation similar to that of martensite. See also *lath martensite* and *plate martensite*.

Martensitic Range

The interval between the martensite start M_s and the martensite finish M_f temperatures.

Martensitic Stainless Steel

See *stainless steels*.

Martensitic Transformation

A reaction that takes place in some metals on cooling, with the formation of an acicular structure called *martensite*.

Mash Resistance Seam Welding

Resistance seam welding in which the weld is made in a lap joint, the thickness at the lap being reduced plastically to approximately the thickness of one of the lapped parts. A resistance seam weld in which the similar thickness sheet components are set up to form an overlap that is mashed, that is, crushed, during welding so that the final weld thickness approximates the thickness of a single sheet.

Mask

A device for protecting a surface from the effects of blasting and/or coating. Masks are generally either reusable or disposable.

Masking Tape

A tape used as a *resist for stopping-off purposes*.

Masonry Cement

A hydraulic cement for use in mortars for masonry construction, containing one or more of the following materials: portland cement, portland blast furnace slag cement, portland-pozzolan cement, natural cement, slag cement, or hydraulic lime. In addition, masonry cement usually contains one or more materials such as hydrated lime, limestone, chalk, calcareous shell, or talc, slag, or clay as prepared for this purpose. See also *cement*.

Mass Absorption Coefficient

The linear absorption coefficient divided by the density of the medium.

Mass Concentration (in a Slurry)

The mass of solid particles per unit mass of mixture, expressed in percent.

Mass Effect (in Steels)

The effect of cooling rate resulting from an increase in mass. See *hardenability*.

Mass–Energy Relationship

The Einstein equation $E = mc^2$, where E is the energy in ergs, m is the mass in g, and c is the velocity of light in cm/s.

Mass Spectrograph

An analytical technique in which ions of the material under test are passed across magnetic and electrostatic fields. The path deflection is recorded as a measure of their composition.

Mass Spectrometer

An instrument that is capable of separating ionized molecules of different mass/charge ratios and measuring the respective ion currents.

Mass Spectrometry

An analytical technique for identification of chemical structures, and analysis of mixtures, and quantitative elemental analysis, based on application of the *mass spectrometer*.

Mass Spectrum

A record, graph, or table that shows the relative number of ions of various masses that are produced when a given substance is processed in a *mass spectrometer*.

Master Alloy

An alloy, rich in one or more desired addition elements, that is added to a metal melt to raise the percentage of a desired constituent.

Master Alloy Powder

A prealloyed metal powder of high concentration of alloy content, designed to be diluted when mixed with a base powder to produce the desired composition. See also *prealloyed powder*.

Master Block

A forging *die block* used primarily to hold insert dies. See also *die insert*.

Master Pattern

In foundry practice, a pattern embodying a double contraction allowance in its construction, used for making castings to be employed as patterns in production work.

Mastic

The gum exudation of the tree called **Chios mastic** and from **Bombay mastic**, both small evergreens native to the Mediterranean countries. It contains an ethereal oil (2%) that is mainly **pinene**. In ancient times, the resin was highly valued for artists' paints and coating lacquers, adhesives, and for incense, dental cements, and as a chewing gum from which use it derives its name. Because of high cost, its use is now largely limited to fine art paints and lacquers and as an astringent in medicine.

Mat

A fibrous glass material used as a plastic reinforcement and consisting of randomly oriented chopped filaments, short fibers (with or without a carrier fabric), or swirled filaments loosely held together

M

with a binder. Available in blankets of various widths, weights, and lengths. Also, a sheet formed by filament winding a single-hoop ply of fiber on a mandrel, cutting across its width and laying out a flat sheet.

Match

A condition in which a point in one metal forming or forging die half is aligned properly with the corresponding point in the opposite die half within specified tolerance.

Match Plate

A plate of metal or other material on which patterns for metal casting are mounted (or formed as an integral part) to facilitate molding. The pattern is divided along its *parting plane* by the plate.

Matched Edges

Two edges of the die face that are machined exactly at 90° to each other, and from which all dimensions are taken in laying out the die impression and aligning the dies in the forging equipment. Also referred to as match lines.

Matched Metal Die Molding

A reinforced plastic manufacturing process in which matching male and female metal molds are used (e.g., in compression molding) to form the part, with time, pressure, and heat.

Matching Draft

The adjustment of draft angles (usually involving an increase) on parts with asymmetrical ribs and side walls to make the surfaces of a forging meet at the parting line.

Materials Characterization

The use of various analytical methods (spectroscopy, microscopy, chromatography, etc.) to describe those features of composition (both bulk and surface) and structure (including defects) of a material that are significant for a particular preparation, study of properties, or use. Test methods that yield information primarily related to materials properties, such as thermal, electrical, and mechanical properties, are excluded from this definition.

Materials Handling

Materials handling involves the loading, moving, and unloading of materials. The loading, moving, and unloading of ore from a mine to a mill and of garments within a factory are examples of materials handling. There are hundreds of different ways of handling materials. These are generally classified according to the type of equipment used. For example, the International Materials Management Society has classified equipment as (1) conveyor; (2) cranes, elevators, and hoists; (3) positioning, weighing, and control equipment; (4) industrial vehicles; (5) motor vehicles; (6) railroad cars; (7) marine carriers; (8) aircraft; and (9) containers and supports.

Every materials-handling problem starts with the material—its dimensions, its nature, and its characteristics. Engineers who fail to start here usually end up trying to justify equipment rather

than achieving safe and economical movement of the material. The quantity to be moved—both in total and the rate of moving desired—is next in selecting the appropriate handling method. Then comes the sequence of operations or the routing. Basically, this what, when (how much and how often), and where is the minimum information needed to evaluate or determine any handling system or equipment.

Materials handling is both a planning and an operating activities. These two activities are generally separated in industry; an analytical group designs or selects the system or equipment, and the operating group puts it to use.

Equipment

This refers to devices used for handling materials in an industrial distribution activity. The equipment moves products as discrete articles, in suitable containers, or as solid bulk materials that are relatively free-flowing. Such equipment does not include the means employed to control the flow of fluids.

Many different types of machines result from combinations and permutations of the following factors:

1. The route over which the product is moved may be fixed or variable.
2. The path of travel may be horizontal, inclined, declined, or vertical.
3. Motion may be imparted to the product manually, by the force of gravity, by air pressure, by vacuum, by vibration, or by power-actuated components of the machine.
4. The motion may be continuous or intermittent (reciprocating).
5. The product may be supported or carried suspended during the handling operation.

Based on their most common characteristics, materials-handling equipment is classified into broad categories: bulk-handling machines, elevating machines, hoisting machines, industrial trucks, and monorail.

Improvements in handling techniques stem from the wide adoption by industry of palletizing and of the forklift truck. These innovations have produced far-reaching effects. Among these are radical changes in plant layout, elevator design for multistory operations, and the increasing trend to single-story facilities.

Automation, in the sense of feedback control and advanced mechanization in the fabrication and transfer of products from one operation to the next, brings together two major industrial technologies.

Computer-controlled electronic data-processing devices facilitate the compiling of inventory records and the handling of orders. Use of photoelectric devices for counting and controlling the action of doors, conveyors, and other materials-handling equipment is another example of how electronic techniques are applied. Television and two-way radio improve the communication for materials handling and plants and yards.

Materials Processing

One of the most promising, fast, low-cost methods for processing materials is known as self-propagating high-temperature synthesis (SHS). Table M.1 presents a comparison of this combustion synthesis process and the other synthetic processes.

Combustion Synthesis

Nonoxide materials (such as carbides, nitrides, borides, chalcogenides, hydrides, intermetallic compounds, and sulfides) have been

TABLE M.1
Comparison of Various Synthesis Processes

Process	Advantages	Disadvantages	Compositions
Carbothermal reduction	Possible automation; some control of chemistry	Can be somewhat energy and capital cost-intensive; usually requires milling, which can produce impurities; large scale-up may be difficult; expensive raw materials	Titanium boride, silicon carbide, other nonoxides
Solid–solid, solid–gas, combustion synthesis	Usually self-propagating (requiring no external heat source) and fast (within seconds)	Exothermic, volatile reactions, sometimes low density or low yields, densification may require high pressures, addition of dopants may be required	Titanium boride, titanium carbide, silicon nitride, other nonoxides, composites
Vapor-phase synthesis	High purity, no aggregation, ease of preparation, narrow size distribution, versatility, homogeneity	Limited chemistry, ternary compounds difficult; low yields; reactant gases expensive	Oxides, nonoxides (nitrides, carbides), metals, binary compounds
Laser synthesis	Wide range of composition, short reaction times, uniform heating rates, improved process control, uniform size distribution, minimum agglomeration	Volatile reactants, expensive equipment, powder yields can be low, contamination a problem for certain reactions	Refractory materials (nitrides, borides, silicides, carbides), transition metal compounds, oxides with other emission lives
Plasma synthesis	Highly efficient, simple, continuous; homogeneous mixtures; high surface areas; oxides with wide range of available starting materials; very fast quench rates	Requires high power (10^3 kW), large capital and operating costs, higher surface areas cause greater pyrophoricity, health hazards due to inhaling, carbides and nitrides are sensitive, low powder yields, some agglomeration, nonreproducibility	Oxides, carbides, nitrides, mixtures (silicon oxide + aluminum nitride, silicon carbide + silicon carbide, aluminum + aluminum nitride)

Source: *Adv. Mater. Proc.*, 131(4), 53, 1987. With permission.

produced by combustion synthesis. This SHS, originally developed in the late 1960s, usually involves exothermic reactions above 2500°C. The combustion process itself can be stable or unstable and does not require a furnace. The high temperatures remove any volatile contaminants by vaporization.

Combustion synthesis can involve several different types of reactions. An oxidation–reduction, or thermite, can produce multiphase composition such as cermets. For example, thermite occurs when a mixture of aluminum powder and iron oxide powder reacts, causing strong heating and yielding aluminum oxide plus a white-hot molten mass of metallic iron.

The thermite reactions have been used to weld metals, as in the welding of cracks in railroad rails.

Synthesis of Refractory Materials

An example of this process is the reaction between transition metals and carbon powders. Upon ignition of the cold-pressed compact, a combustion wave rapidly (several seconds) propagates through the mass, converting the reactants to metal carbides (Figure M.3). Besides carbides, β -sialon, and micro composites, silicon carbide + aluminum oxide and titanium carbide + aluminum oxide have been formed.

As a class of refractory materials, the nitrides, such as aluminum nitride, titanium nitride, zirconium nitride, hafnium nitride, boron nitride, and silicon nitride, have all been formed by SHS. The process for synthesizing nitrides proceeds in a fairly predictable manner. The metal powders are cold-pressed into porous compacts. Subsequently, these compacts are ignited in nitrogen gas or liquid

nitrogen by a resistance-heated tungsten wire. The self-propagating combustion wave quickly transforms a metal powder into porous solid nitrides.

Control of Synthesis

Of four innovations to control the synthesis reactions, one is used to slow down (kinetic braking) and three to intensify the reactions (thermal explosion, chemical furnace, and chemical activators).

Other Self-Propagating High-Temperature Synthesis Processes

- Reaction hot pressing, which utilizes SHS reactions in place in a uniaxial hot press to form densified ceramic products. Reaction hot pressing takes advantage of the favorable thermodynamics of SHS reactions to rapidly form an densify product phases.
- Reactive sintering, which occurs when pressure is applied during sintering. The process is also known as reactive hot isostatic pressing.
- Shock compression, where chemical reactions can also be initiated by shock compression of powder mixtures. This type of dynamic processing technique, referred to as shock-induced reaction synthesis, utilizes the simultaneous application of very high pressure and temperature generated during the passage of shock waves through a powder mixture.

M

Materials Science and Engineering

This is a multidisciplinary field concerned with the generation and application of knowledge relative to the composition, structure, and processing of materials and their properties and uses. The field encompasses the complete knowledge spectrum for materials ranging from the basic end (materials science) to the applied end (materials engineering). It forms a bridge of knowledge from the basic sciences (and mathematics) to various engineering disciplines. New materials with special properties are constantly being discovered and developed, and thus materials science and engineering is a continually expanding field.

Metallic Materials

The study of metallic materials constitutes a major division of the material science and engineering field. In general, metallic materials are inorganic substances composed of one or more metallic elements, but they may also contain nonmetallic elements. Most metals have a crystalline structure of closely packed atoms arranged in an orderly manner. Metals in general are good electrical and thermal conductors. Many are relatively strong at room temperature and retain good strength at elevated temperatures. Metals are commonly alloyed together in the liquid state so that, upon solidification, new solid metallic structures with different properties can be produced. Metals and alloys are often cast into the nearly final shape in which they will be used, and these products are called castings. However, most metals and alloys are first cast into shapes such as sheet ingots or extrusion billets, which are subsequently worked by processes such as rolling and extrusion into wrought products, for example, sheet, plate, and extrusions.

Ceramic Materials

The study of ceramic materials forms a second major division of the field of materials science and engineering. Ceramics are inorganic materials consisting of metallic and nonmetallic elements chemically bonded together. They can be crystalline, noncrystalline, or mixtures of both. Most ceramic materials have high hardness, high-temperature strength, and good chemical resistance; however, they tend to be brittle.

Ceramics in general have low electrical and thermal conductivities, which makes them useful for electrical and thermal insulative applications. Most ceramic materials can be classified into three groups: traditional ceramics, technical ceramics, and glasses.

Traditional Ceramics

These consist of three basic components; clay, silica, and feldspar. The clay provides the workability of the ceramic before it is hardened by the firing process. Clay makes up the major body material; it consists mainly of hydrated aluminum silicates ($\text{Al}_2\text{O}_3 \cdot \text{SiO}_2 \cdot \text{H}_2\text{O}$) with smaller amounts of other oxide impurities. The silica (SiO_2) has a high melting temperature and provides the refractory component of traditional ceramics. The third component, feldspar ($\text{K}_2\text{O} \cdot \text{Al}_2\text{O}_3 \cdot 6\text{H}_2\text{O}$), has a low melting temperature and produces a glass when the ceramic mix is fired; it bonds the refractory components together. Traditional ceramic products fabricated from white-ware such as electrical porcelain and sanitaryware are made from components of clay, silica, and feldspar for which the composition is controlled.

Technical Ceramics

Technical ceramics are based on pure or nearly pure ceramic components alone or in combination. The raw materials for technical

ceramics must be processed carefully so that a controlled product can be produced, and they are made by using various composition mixes and processing procedures. Examples of technical ceramics are aluminum oxide (Al_2O_3), zirconia (ZrO_2), silicon carbide (SiC), silicon nitride (Si_3N_4), and barium titanate (BaTiO_3). Applications for technical ceramics include aluminas for auto spark-plug insulators and substrates for electronic circuitry, dielectric materials for capacitors, ceramic tool bits for machining, and high-performance ball bearings.

Glasses

Glasses differ from the other ceramic materials in that their constituents are heated to fusion and then cooled to a rigid state without crystallization. A characteristic of a glass is that it has a noncrystalline structure with no long-range order. Many inorganic glasses are based on the glass-forming silicon oxide, silica (SiO_2). About 90% of the glass produced is soda-lime glass, which is the basic composition of 1%–3% SiO_2 , 12%–14% sodium oxide (Na_2O), and 10%–12% calcium oxide (CaO). The sodium oxide and calcium oxide are added to lower the viscosity of the glass so that it becomes easier to work. Soda-lime glass is used, for example, for flat glass, containers, and light products, where high chemical durability and heat resistance are not required. Many other types of glasses with different compositions are produced for specialized applications.

Polymeric Materials

The study of polymeric materials forms a third major division of materials science and engineering. Most of these materials consist of carbon-containing long molecular chains or networks. Structurally, most of them are noncrystalline, but some are partly crystalline. The strength and ductility of polymeric materials vary greatly. Most polymers have low densities and relatively low softening or decomposition temperatures. Many are good thermal and electrical insulators. Polymeric materials have replaced metals and glasses for many applications.

Most polymeric materials can be classified as thermoplastics, thermosets, or elastomers.

Thermoplastics

These are polymeric materials that have a structure usually consisting of very long chains of carbon atoms strongly (covalently) bonded together, sometimes with other atoms, such as nitrogen, oxygen, and sulfur, also covalently bonded in the molecular chains. Weaker secondary bonds bind the chains together into a solid mass. Because of their weak intermolecular bonds, thermoplastics can be heated to a soft, viscous condition for forming into a desired shape and then cooled to a rigid state to retain that shape. Typical thermoplastics are polyethylenes, polyvinyl chlorides, and polyamides (nylons). Some examples of applications for thermoplastics are containers, electrical insulation, automotive internal parts, and appliance housings.

Thermosets

These are polymeric materials that have a network of mainly carbon atoms covalently bonded together to form a rigid solid. Sometimes, nitrogen, oxygen, or other atoms are also covalently bonded into the network. Thermosets are formed into a permanent shape and are cured (set) by a chemical reaction that may require heat and pressure. Thermoset plastics cannot be remelted or reformed into another shape after curing. Thermosets such as phenolics (e.g., Bakelite) and epoxies are used for handles, knobs, electrical connectors, and matrix materials for fiber-reinforced plastics.

Elastomers

This class of materials, also known as rubbers, can be deformed elastically by a large amount when a force is applied to them, and then they can return to approximately the same shape when the force is removed. Most elastomers consist of long, carbon-containing molecular chains with periodic strong bond links between the chains. Elastomers include both natural and synthetic rubbers, which are used for auto tires, electrical insulation, and industrial hoses and belts.

Composite Materials

A fourth major division of materials science and engineering comprises the study of composite materials. A composite material is a mixture of two or more materials that differ in form and chemical composition and are essentially insoluble in each other, and most are produced synthetically by combining various types of fibers with different matrices to increase strength, toughness, and other properties. Three important types of composite materials have polymeric, metallic, and ceramic matrices.

Polymeric-matrix composites are the most common type and find most applications where the temperature does not exceed about 100°C–200°C. For example, glass-fiber materials produced with short glass fibers embedded in a polyester plastic matrix are used in appliances, boats, and car bodies because of their light weight, ease of fabrication into complex shapes, corrosion resistance, and moderate cost. Other more expensive advanced composites made with stronger carbon or aramid fibers, usually embedded in heat-resistant thermoset polymeric matrices, are used for aircraft surface material and structural members. Advanced polymeric-matrix composites are also finding use in sports equipment and other products, but their high cost has limited their use.

Metal-matrix composites (MMCs) have also been developed by embedding fibers such as silicon carbide and aluminum oxide into aluminum, magnesium, and other metal alloy matrices. The fibers strengthen the metal alloys and increase high-temperature stability. MMCs are used, for example, for automotive pistons and missile guidance systems. Ceramic-matrix composites have also been considered to develop new and tougher ceramic materials. For example, the reinforcement of alumina with silicon carbide whiskers significantly improves its fracture toughness and strength.

Other Materials

In addition to metallic, ceramic, polymeric, and composite materials, materials science and engineering is also concerned with the research and development of other special classes of materials that are based on applications. Some major types of these materials are electronic materials, optical materials, magnetic materials, superconducting materials, dielectric materials, nuclear materials, biomedical materials, and building materials.

Matrix (Adhesives)

The part of an adhesive that surrounds or engulfs embedded filler or reinforcing particles and filaments.

Matrix (Composites)

The essentially homogeneous plastic resin in which the fiber reinforcement is embedded. Both thermoplastic and thermoset resins may be used.

Matrix (Metals)

The continuous or principal phase in which another constituent is dispersed.

Matrix Isolation

A technique for maintaining molecules at low temperature for spectroscopic study; this method is particularly well suited for preserving reactive species in a solid, inert environment.

Matrix Metal

The continuous phase of a polyphase alloy, mechanical mixture, or MMC; the physically continuous metallic constituent in which separate particles of another constituent are embedded.

Matte

(1) An intermediate product of *smelting*; an impure metallic sulfide mixture made by melting a roasted sulfide ore, such as an ore of copper, lead, or nickel. (2) A matte surface is level but dull and diffuses rather than reflects light.

Matte Dip

An etching solution used to produce a dull finish on metal.

Matte Finish

(1) A dull texture produced by rolling sheet or strip between rolls that have been roughened by blasting. (2) A dull finish characteristic of some electrodeposits, such as cadmium or tin.

Mauritius Hemp

The fiber obtained from the fleshy leaves of the plant grown in Mauritius, Nigeria, and Ghana, used for rope and cordage. The product from West Africa is often erroneously termed *sisal*. The plant belongs to the lily family. The leaves yield up to 3.5% of their green weight in dry fiber, which is coarser than henequen but is used for coffee-bag fabric. The fibers are used extensively for burlap for bagging. **Fique fiber**, of Columbia used for rope and coffee bags, is from the leaves of *F. macrophylla*. The leaves are longer than those of henequen, and the fiber is finer and more lustrous.

Maximum Elongation

The elongation at the time of fracture, including both elastic and plastic deformation of the tensile specimen. Applicable to rubber, plastic, and some metallic materials. Maximum elongation is also called ultimate elongation or break elongation.

Maximum Erosion Rate

The maximum instantaneous erosion rate in a test that exhibits such a maximum followed by decreasing erosion rates. Occurrence of such a maximum is typical of many cavitation and liquid impingement tests. In some instances, it occurs as an instantaneous maximum; in others, it occurs as a steady-state maximum that persists for some time.

FIGURE M.3 Illustration of SHS. (From *McGraw-Hill Handbook of Structural Ceramics*, McGraw-Hill, New York, 1992, p. 423. With permission.)

Maximum Load Rate ($P_{\max}$)

(1) The load having the higher algebraic value in the load cycle. Tensile loads are considered positive and compressive loads negative. (2) Used to determine the strength of a structural member; the load that can be borne before failure is apparent.

Maximum Pore Size

See *absolute pore size*.

Maximum Rate Period

In cavitation and liquid impingement erosion, a stage following the acceleration period, during which the erosion rate remains constant (or nearly so) at its maximum value.

Maximum Strength

See *ultimate strength*.

Maximum Stress ($S_{\max}$)

The stress having the highest algebraic value in the stress cycle, tensile stress being considered positive and compressive stress negative. The *nominal stress* is used most commonly.

Maximum Stress Intensity Factor ($K_{\max}$)

The maximum value of the *stress-intensity factor* in a fatigue cycle.

Maximum Tensile Stress

Same as *ultimate tensile strength*. See *tensile test*.

Mazac Alloy

A proprietary range of alloys based on zinc with about 4% aluminum and minor additions of copper and magnesium. They have excellent die casting characteristics.

McQuaid-Ehn Grain Size

The austenitic grain size developed in steels by carburizing at 927°C (1700°F) followed by slow cooling. Eight standard McQuaid-Ehn grain sizes rate the structure, from No. 8, the finest, to No. 1, the coarsest. The use of standardized ASTM methods for determining grain size is recommended. The prior austenitic grain size of the Hyper Eutectoid carburizing case is readily established by metallographic examination.

Mean Free Path

The average distance between collisions for an electron or molecule.

Mean Stress (S_m)

The algebraic average of the maximum and minimum stresses in one cycle, that is, $S_m = (S_{\max} + S_{\min})/2$. Also referred to as steady component of stress. See *fatigue*.

Mechanical Activation

The acceleration or initiation of a chemical reaction by mechanical exposure of a nascent solid surface. Metal cutting (machining) is an effective method of exposing large areas of fresh surface.

Mechanical Adhesion

Adhesion between surfaces produced solely by the interlocking of protuberances on those surfaces. See also *adherence*.

Mechanical Alignment

A method of aligning the geometrical axis of the electron microscope by relative physical movement of the components, usually as a step preceding magnetic or voltage alignment. See also *alignment*.

Mechanical Alloying

The application of powder metallurgy (P/M) techniques has greatly increased in recent years. In many cases, P/M allows for metal parts

to be produced at lower cost with improved properties. Another advantage that P/M offers is that it can produce alloys and microstructures that are not possible to produce by standard metallurgical practices such as casting and forging. An important area of P/M is the production of the metal powders used. The physical and chemical nature of the initial powders will determine many of the final properties of the P/M parts produced.

Mechanical alloying is a materials-processing method that involves the repeated welding, fracturing, and rewelding of a mixture of powder particles, generally in a high-energy ball mill, to produce a controlled, extremely fine microstructure. The mechanical alloying technique allows alloying of elements that are difficult or impossible to combine by conventional melting methods. In general, the process can be viewed as a means of assembling metal constituents with a controlled microstructure. If two metals will form a solid solution, mechanical alloying can be used to achieve this state without the need for a high-temperature excursion. Conversely, if the two metals are insoluble in the liquid or solid state, an extremely fine dispersion of one of the metals in the other can be accomplished. The process of mechanical alloying was originally developed as a means of overcoming the disadvantages associated with using P/M to alloy elements that are difficult to combine. By using P/M, homogeneity is dictated by the size of the particle, but contamination and fire hazards become a concern when particle size is very small.

Process

The process of mechanical alloying consists of repeated flattening, fracture, and rewelding of the powder particles in a high-energy ball charge. Every time two steel balls collide, they trap powder particles between them. This deforms the particles and creates minimal foreign species on the surface so that welding together of adjacent surfaces can occur easily. The alloying is affected by the ball-powder-ball collisions in several stages. In the first stage, intense cold welding predominates, and layered composite particulates of the starting constituents form. This is followed by a hardening of the particles and fracturing and cold welding leading to a finer composite particle size. Solid-solution formation begins at this stage. Next, in a moderate cold welding period, the microstructure of the particles gets finer, with a typical spacing between adjacent regions of 1 μm the compositions of the individual particles converge to the original blend composition, with the rate of refinement of the internal structure (reduction in scale of the microstructure) of the particles approximately logarithmic with processing time. The final stage is a steady-state period. By the time processing has been completed, the particles have an extremely deformed metastable structure, which can contain dispersoids. Generally, at this point, the microstructural scale is significantly below the micrometer level.

Applications

Some oxides are insoluble in molten metals. Mechanical alloying was originally developed to provide a means of dispersing these oxides in the metals. Examples are nickel-based superalloys that strengthened with dispersed thorium oxide or yttrium oxide (Y_2O_3), the latter being preferred. These superalloys have excellent strength and corrosion resistance at elevated temperatures, making them attractive candidate materials for use in applications such as jet-engine turbine blades, vanes, and combustors. This class of alloys is known as oxide-dispersion-strengthened (ODS) nickel-base superalloys. Iron- and aluminum-base dispersion-strengthened alloys have also been developed. Additionally, a number of other potential applications of mechanical alloying materials has been explored, including powders for coating applications, alloys of immiscible systems,

amorphous alloys, intermetallics, cermets, and organic-ceramic-metallic materials systems in general.

Alloys like MA 754 (Ni-20%, Cr-0.3%, Al-0.5%, Ti-0.6%, Y_2O_3) and MA 6000 (Ni-15%, Cr-4%, W-2%, Mo-2%, Ta-4.5%, Al-2.5%, Ti-1.1%, Y_2O_3) are commercially available as bar and plate for use in gas turbine vanes and turbine blades and for other applications in oxidizing or corrosive atmospheres. The vane alloy MA 754 is capable of withstanding a surface temperature of about 1100°C and is used in military engines. The iron-base alloy MA 956 (Fe-20%, Cr-4.5%, Al-0.5%, Ti-0.5%, Y_2O_3), available as plate sheet, bar, and wire, is capable of withstanding temperatures up to 1300°C or even higher in corrosive environments; it has applications in aircraft and industrial gas turbine combustors, in swirlers and heat exchangers of power generation equipment, and in heat-treatment equipment.

Conventional coatings in advanced gas turbine engines fail by loss of aluminum in the coating or by interdiffusion between the coating and substrate. Coatings possessing a large amount of Y_2O_3 , produced by mechanical alloying, could solve such problems.

Liquid or solid immiscible systems are difficult to process by conventional pyrometallurgy, for example, the copper-lead or copper-iron systems. In these cases, mechanical alloying provides a route to obtain a homogeneous distribution in the solid phase. Mechanical alloying has also been used to fabricate the superconducting intermetallic niobium-tin compound Nb_3Sn , which is difficult to produce conventionally because of the large melting point difference between niobium and tin. Mechanical alloying can also be used to produce supercorroding magnesium-base alloys. These alloys are designed to corrode at a controlled rate for release of deep-sea equipment at specific depths. The requirement is to have the anode and cathode in proximity by using mechanical alloying. In another interesting application of mechanical alloying, titanium and magnesium have been combined by using mechanical alloying; usually, it is very difficult to produce such an alloy because the boiling point of magnesium is lower than the melting point of titanium. This achievement could result in a lower-density titanium alloy for aerospace applications.

Amorphous alloys can also be produced by using the mechanical alloying technique. These include Nb_3Sn starting from elemental powders, various rare earth-cobalt combinations, and titanium-copper and titanium-copper-palladium systems. See also *attritor grinding* and *dispersion-strengthened material*.

Mechanical Bond (Thermal Spraying)

The adherence of a thermal sprayed deposit to a roughened surface by the mechanism of particle interlocking.

Mechanical (Cold) Crack

A crack or fracture in a casting resulting from rough handling or from thermal shock, such as may occur at shakeout or during heat treatment.

Mechanical Disintegration

See preferred terms *comminution* and *pulverization*.

Mechanical Finishes

Finishing with Coated Abrasives

Coated abrasives or “sandpaper” can be used in many ways on many materials to produce a wide variety of finished surfaces. The method

M

of application as well as the type of abrasive used greatly influences the results obtained. Following is a description of the three principal methods of using endless abrasive belts and the application for each method.

Contact Wheel Application

The contact wheel method produces the best abrasive efficiency, including the fastest rate of cut and the best abrasive life. The finish produced by this method is characterized by short individual scratches that are uniform across the width of contact and in line with the running direction of the belt. This method can be used on all types of parts having flat or lightly contoured surfaces such as hand tools, small household appliances, cutlery, and stainless steel sheet for decorative trim and kitchens, hospitals, etc.

Platen Method

This method is used for finishing work with a flat surface that is either continuous or interrupted. Because individual abrasive grain remains in contact with the work from top to bottom, the method produces a continuous scratch running the length of the part in contact with the belt. The advantage of the platen method is that the whole surface is contacted simultaneously and it easily produces flatness with a high degree of accuracy.

Slack Belt

This method is used on work that is highly contoured such as metal furniture, light fixtures, and plumbing fixtures. The flexibility of the belt is useful in polishing hard-to-reach surfaces where contours and shapes are involved. The length of scratch pattern produced is between the short scratch pattern of the contact wheel method and the long scratch pattern of the platen.

Types of Abrasives and Finishes

Two principal types of abrasives are used for coated-abrasive types of finishing operations—aluminum oxide and silicon carbide. The former has a blocky shape and is very tough. It is used for grinding and finishing materials having a high tensile strength. Silicon carbide is harder and sharper but is more friable or brittle; consequently, it is used for grinding and finishing materials having low tensile strength.

Coated abrasives are used extensively for a vast multitude of grinding and finishing operations because of their inherent versatility and economy. The finishes produced with coated abrasives are primarily decorative but can also be used for functional purposes in cases where geometry of the finished parts is important.

Finishing with Loose Abrasives

Finishes produced by loose abrasives, such as aluminum oxide and silicon carbide, are available in many variations of surface roughness and appearance, depending on the methods used. The methods used to produce or polish a surface may include polishing wheels (referred to as “setup” wheels), lapping, pressure blasting, and barrel finishing (often referred to as tumbling).

Setup wheels can be likened to bonded grinding wheels. The basic difference is that setup wheels are resilient because they are made of cloth laminations that are stitched so as to give a certain rigidity or resiliency. Abrasive grain is cemented on the periphery of setup wheels with cold cement or hot glue. Because of its “cushioning” effect, the resiliency of setup wheels simplifies the blending of contoured surfaces.

Buffing

Buffing with loose abrasives usually follows a polishing operation, with the latter done with either setup wheels or coated belts. Buffing generates smooth surfaces that are essentially free of scratches and have high reflectivity. It is accomplished by bringing the surface into contact with the periphery of a buffing wheel (usually cloth laminations) to which abrasive materials have been applied in composition form. Buffing generates smooth and reflective surfaces by removing or displacing relatively small amounts of metal. It is not designed to establish or retain dimensional accuracy.

Pressure Blasting

Pressure blasting is the process in which solid abrasive particles are propelled against a surface by means of expanding compressed air. The method always produces a matte finish. The finer the abrasive, the finer the finish, the coarser the abrasive, the faster the rate of stock removal and the rougher the finish.

Pressure blasting can be used for many finishing purposes. These include removal of heat-treat scale and oxides from metallic surfaces, preparation of surfaces for protective coatings, removal of contamination from nuclear devices, generation of decorative finishes, preparation of surfaces for visual inspection for surface defects, and removal of small burrs.

Lapping

Lapping can be used to produce very smooth finishes and geometrically true surfaces. Like grinding, the degree of finish obtained by lapping can be controlled by the particle size of the abrasive. Coarse grits plow deep furrows and therefore remove stock faster than fine particles. Fine particles, conversely, remove stock at a lower rate but produce finishes with a lower root mean square (rms). To reduce the surface roughness from, for example, 30–5 rms, usually requires using 2–3 progressively finer abrasives.

The finishes generated by lapping are functional rather than decorative. The surface smoothness dictates a low rms where wearing parts are involved. Flatness and scratch-free parts are essential for components such as high-pressure valves, and germanium and silicon transistor wafers.

Barrel Finishing

Barrel finishing is a surface-conditioning operation in which a mixture of metallic or nonmetallic parts, abrasive media, and various compounds is placed in a receptacle and rotated for the purpose of rounding corners, deburring, improving surface finish, cleaning, derusting, burnishing for high luster, and producing low microinch finishes. Many of these finishing operations are accomplished in simultaneous operations.

Unlike grinding wheel, setup wheel, or abrasive belt operations, tumbling produces a random scratch pattern. This is because the media and parts have a random motion while the barrel is rotating. But like grinding wheels and other types of abrasive finishing methods, the types and size of abrasive media (sometimes called nuggets, pellets, chips, etc.) influence the roughness and rate of stock removal.

Finishing with Bonded Abrasives

Finishes produced by grinding wheels vary over a wide range both in surface roughness and in surface appearance. These finishes can be divided into two major classifications: those produced by rough grinding and those produced by finish grinding.

Rough-grinding operation is primarily intended for stock removal without any particular regard for appearance. The finish produced can be described as having the appearance of a plowed field with the direction of the furrows in the same direction as the path of the grinding wheel. The depth of the furrows is in direct proportion to the roughness of the grind. The rougher the grind, the deeper the furrow; the less severe the grind, the shallower the furrow. The surface roughness produced by rough grinding varies over a wide range, beginning in the 30 $\mu\text{in.}$ area and becoming progressively rougher.

Finish grinding, as its name implies, is used for the production of finish and, in addition, the generation of geometry. This finish may be one that has a low surface roughness or a high luster and, in some cases, both a low roughness and a high luster.

The appearance of a finely ground surface can either be a dull matte finish, or it can be a highly reflective surface. A distinction is made between the roughness of the dull matte ground finish and that of a highly reflective ground surface. A dull matte finish is generally smooth and many times, smoother than a highly reflective surface. The matte finish is a truly ground surface and can be described as a plowed field where the furrows are very shallow in depth and all the ridges have been removed.

A highly reflective surface, on the other hand, can be described as a plowed field where some of the ridges have fallen into the adjacent furrow and are pushed into that furrow by the grinding wheel as it passes over it. This produces a luster but not necessarily a low surface roughness.

Mechanical Hysteresis

Energy absorbed in a complete cycle of loading and unloading within the elastic limit and represented by the closed loop of the stress-strain curves for loading and unloading. Sometimes referred to as elastic, but more properly, mechanical. See also the term *hysteresis loop* (mechanical).

The phenomenon by which a material deformed in tension within its elastic range does not return immediately to zero strain on removal of the load. Further loading in elastic compression and then repeating the tensile load cause the stress-strain relationship to follow a hysteresis loop. The larger the area contained in the loop, the greater is the energy consumed and the greater the damping. The effect is related to the *elastic after effect*.

Mechanical Metallurgy

The science and technology dealing with the behavior of metals when subjected to applied forces; often considered to be restricted to plastic working or shaping of metals.

Mechanical Plating

Plating wherein fine metal powders are peened onto the work by *tumbling* or other means. The process is used primarily to provide ferrous parts with coatings of zinc, cadmium, tin, and alloys of these metals in various combinations. The process takes place in a rotating barrel with balls or powder of the plating metal. The metal plating is applied by mechanical means rather than electroplating or dip processes.

Mechanical Polishing

A process that yields a specularly reflecting surface entirely by the action of machining tools, which are usually the points of abrasive particles suspended in a liquid among the fibers of a polishing cloth.

Mechanical Press

A press to slide is operated by a crank, eccentric, cam, toggle links, or other mechanical device. See the term *eccentric gear*, *knuckle-lever press*, and *toggle press*.

Mechanical Press Brake

A *press brake* using a mechanical drive consisting of a motor, fly-wheel, crankshaft, clutch, and eccentric to generate vertical motion.

Mechanical Properties

The properties of a material that reveal its elastic and inelastic behaviors when force is applied, thereby indicating its suitability for mechanical applications; for example, modulus of elasticity, tensile strength, elongation, hardness, and fatigue limit, bend, impact, and torsion. Compare with *physical properties*.

Mechanical Seal

See *face seal*.

Mechanical Stability (of a Grease)

Grease shear stability tested in a standard rolling tester.

Mechanical Stage

In microscopy, a device provided for adjusting the position of a specimen, usually by translation into directions at right angles to each other.

Mechanical Testing

Any testing to determine the mechanical properties of a material, particularly tensile testing but including bend, impact, fatigue, and creep testing. The term usually includes hardness testing since this can give an accurate indication of some mechanical properties.

Mechanical Twin

A *twin* formed in a crystal by simple shear on the external loading. See *twin*.

Mechanical Upsetter

A three-element forging press, with two gripper dies and a forming tool, for flanging or forming relatively deep recesses.

Mechanical Wear

Removal of material due to mechanical processes under conditions of sliding, rolling, or repeated impact. The term mechanical wear includes *adhesive wear*, *abrasive wear*, and *fatigue wear*. Compare with *corrosive wear* and *thermal wear*.

Mechanical Working

The subjecting of metals to pressure exerted by rolls, hammers, or presses in order to change the shape or physical properties of the metal.

M

Mechanically Formed Plastic

A cellular plastic having a structure produced by physically incorporated gases.

Median Crack

Damage produced in glass by the static or translational contact of a hard, sharp object on the glass surface. The crack propagation into the glass perpendicular to the original surface.

Median Fatigue Life

The middle value when all of the observed fatigue life values of the individual specimens in a group tested under identical conditions are arranged in order of magnitude. When an even number of specimens are tested, the average of the two middlemost values is used. Use of the sample median rather than the arithmetic mean (i.e., the average) is usually preferred.

Median Fatigue Strength at N Cycles

An estimate of the stress level at which 50% of the population would survive N cycles. The estimate is derived from a particular point of the fatigue life distribution since there is no test procedure by which a frequency distribution of fatigue strengths at N cycles can be directly observed. Also known as *fatigue strength at N cycles*.

Meehanite

Proprietary name for a range of cast irons. The term is used casually referring to inoculated irons.

Meerschaum

A soft, white or gray, claylike mineral of composition $3\text{SiO}_2 \cdot 2\text{MgO} \cdot 2\text{H}_2\text{O}$, used for making pipes and cigar holders, but also employed for making various other articles, as it can be cut easily when wet and withstands heat. When fresh, the mineral absorbs grease and makes a lather, its German name means seafoam. It is used as a filler in soaps in Germany. The hardness is about Mohs 2 and the specific gravity 1.28. Most of the commercial meerschaum comes from Asia Minor, and the mines at Eskisehir have been worked for 20 centuries. **Artificial meerschaum** is made from meerschaum shavings, kieselguhr, and from silicates of aluminum, calcium, and magnesium.

Mega

As a prefix to units of the SI and other systems of units, it is 1 million. For example, Mega-Pascal.

Megaelectron Volt (MeV)

A unit of energy usually associated with a particle. The energy gained by an electron accelerated across 1,000,000 V.

Melamine Formaldehyde Plastics

The outstanding features of melamines, one of the amino resins, include excellent colorability, high hardness, and good electrical characteristics, including exceptional arc resistance.

Primary use is for melamine plastics as engineering materials are in decorative molded dinnerware, decorative thermosetting laminates, molded housings, and wiring devices, closures, and buttons.

The resins are produced by reaction of melamine and formaldehyde. Crystals of melamine, an amino chemical, are reacted with formaldehyde and mixed with highly purified filler, dried, and ground. Color pigments, plasticizers, lubricant, and accelerators are added to produce the molding compound. Melamine is similar in many respects to urea-formaldehyde. Melamine resists water absorption and chemical attack to a greater extent than urea, and its cost is higher.

Applications

Molding Compounds

For molding applications, the hardness and colorability of melamine are outstanding advantages. Melamine is the hardest of plastics (Rockwell M118–M124) and has unlimited colorability. Parts can be produced in any color in the spectrum (both translucent and opaque). Color quality ranges from pastels to bright, jewel-like tones, as well as two tones in the same object. Products such as dishes and tableware can be decorated by foil inlays.

Dinnerware (dishes, plates, cups, and saucers) make up 90% of the uses for melamine molding compounds. Hardness and colorability as well as resistance to attack by foods, detergents, and hot water account for its popularity in the home.

Melamine molding compounds are widely used as handles for flatware and kitchen utensils because of hardness, color, and resistance to heat and water. Handles can now be decorated with patterns applied integrally by foil.

Agitators for washing machines are being molded of melamines because of their resistance to hot water and detergents and excellent appearance. A colored agitator is more attractive than a black one.

Nondecorative applications for molding compounds include wiring fixtures and other electrical uses, where the arc resistance and nontracking characteristics of melamine, coupled with its nonflammability, make it useful. For such uses, strength and impact resistance are improved by incorporating fabrics and glass-fiber reinforcements.

High-Pressure Laminates

The majority of top-quality decorative thermosetting laminates, or high-pressure laminates (e.g., “Formica,” “Micarta,” and “Textolite”), use melamine resins impregnated in alpha-cellulose paper or other clear reinforcements to provide their decorative surfaces. With the proper resin selection, such laminates can be burn and stain resistant. Further, the high hardness of melamines makes them scuff and mar resistant.

Melamine Resin

This is a synthetic resin of the alkyd type made by reacting melamine with formaldehyde. The resin is thermosetting, colorless, odorless, and resistant to organic solvents. It is more resistant to alkalis and acids than urea resins, has better heat and color stability, and is harder. The melamine resins have the greater general uses of molding plastics and also are valued for dishes for hot foods or acid juices, and they will not soften or warp when washed in hot water.

The melamine resins have good adhesiveness but are too hard for use alone in coatings and varnishes. They are combined with alcohol-modified urea-formaldehyde resins to give coating materials of good color and gloss, flexibility, and chemical resistance. Urea-modified melamine-formaldehyde resins are used for coatings

and varnishes. Melamine–formaldehyde molding resin, with cellulose filler, has a tensile strength of 51 MPa and dielectric strength per mil of 12.8×10^6 V/m.

Melamine–urea–formaldehyde resin with a lignin extender is used as an adhesive for water-resistant plywood. Phenyl-modified melamine–formaldehyde resin solution is used for laminating fibrous materials. Highly translucent melamine–formaldehyde resin is used for molding high-gloss buttons. Methylol–melamine, made by alkylating a melamine–formaldehyde resin with methyl alcohol, is used for shrink-proofing woolen fabrics.

Melt

(1) To change a solid to a liquid by the application of heat. (2) A charge of molten metal or plastic. (3) In submerged arc welding, the molten flux above the weld metal.

Melt Index

The amount, in grams, of a thermoplastic resin that can be forced through a 2.0955 mm (0.0825 in.) orifice when subjected to 20.7 N (2160 gf) in 10 min at 190°C (375°F).

Melt Lubrication

Lubrication provided by steady melting of a lubricating species. Also known as *phase-change lubrication*.

Melt Run (of Weld)

A line of parent metal that has been fused without the addition of filler.

Melt Strength

The strength of a plastic while in the molten state.

Meltback Time

In arc welding, the time interval at the end of crater fill time to arc outage during which the electrode feed is stopped. Arc voltage and arc length increase and current decreases to zero to prevent the electrode from freezing in the weld deposit.

Melting Point (Metals)

The temperature at which a pure metal, compound, or eutectic changes from solid to liquid; the temperature at which the liquid and the solid are at equilibrium.

Melting Point (Plastics)

The term that refers to the first-order transition in crystalline polymers. The fixed point between the solid and liquid phases of a material when approached from the solid phase under a pressure of 101.325 kPa (1 atm).

Melting Pressure (Metals)

At a stated temperature, the pressure at which the solid phases of an element or congruently melting compound may coexist at equilibrium with liquid of the same composition.

Melting Range (Metals)

The range of temperatures over which an alloy other than a compound or eutectic changes from solid to liquid; the range of temperatures from *solidus* to *liquidus* at any given composition on a *phase diagram*.

Melting Rate

In electric arc welding, the weight or length of electrode melted in a unit of time. Sometimes called melt-off rate or burn-off rate.

Melting Temperature (Glass)

The range of furnace temperatures within which melting takes place at a commercially desirable rate and within which the resulting glass generally has a viscosity of $10^{0.5}$ – $10^{1.5}$ Pa s ($10^{1.5}$ – $10^{2.5}$ P). To compare the melting temperatures of glasses, it is assumed that a glass at its melting temperature has a viscosity of 10 Pa s (10^2 P).

Melting Temperature (Metals)

See *melting point* (metals).

Melt-Off Rate

See *melting rate*.

Melt-Through

Complete joint penetration for a joint welded from one side. To prevent melt-through, the welding current and the width of the root opening should be reduced and travel speed increased.

Membrane

Any thin sheet or layer.

Memory Alloys

See *shape memory*.

Mendeléev's (Periodic) Table

See *Periodic Table*.

Menstruum Method

A method of producing multicarbide powder, such as WC + TiC solid solution, by introducing the individual elements into a molten bath of a noncarbide-forming metal such as cobalt or nickel. The multicarbide is formed above 2100°C (3800°F), slowly cooled in the dispersed condition in the Menstruum to room temperature, and finally processed by chemical separation.

Mer

The repeating structural unit of any polymer.

Merchant Iron

Multiple forged and hence high-grade wrought iron.

M

Mercury

Mercury (symbol Hg), also called quicksilver, is a metallic element. It is the only metal that is a liquid at room temperature. Mercury has a silvery-white color and a high luster. Its specific gravity is 13.596. The solidifying point is -40°C , and its boiling point at 1 atm is 357°C . It does not oxidize at ordinary temperatures, but when heated to near its boiling point it absorbs oxygen and is converted into mercuric oxide, HgO , used as a pigment in marine paints.

Metallic mercury is used as a liquid contact material for electrical switches, in vacuum technology as a working fluid of diffusion pumps, for the manufacture of mercury-vapor rectifiers, thermometers, barometers, tachometers, and thermostats, and for the manufacture of mercury-vapor lamps. Mercury-vapor lamps serve as sources for ultraviolet light.

For micro gas analyses, mercury is most often used as a sealing liquid for the evolved gases. Very large amounts of mercury are used as the electrode material for the electrolysis of aqueous solutions of alkali halides for the manufacture of chlorine and sodium hydroxide. Also, it finds application for the manufacture of silver amalgams for tooth fillings in dentistry.

Some mercury salts serve as catalysts for organic chemical reactions. Fulminate of mercury is used as a primer for explosives. Some complex salts find application as temperature indicators.

A large number of mercury compounds have been used for hundreds of years as medicines. The compounds of mercury with some organic substances are powerful diuretic substances and have applications as a disinfectant, and ammoniated mercury is used in the treatment of various diseases.

Of importance and electrochemistry are the standard calomel electrode, used as a reference electrode for the measurement of potentials and for potentiometric titrations, and the Weston standard cell, metallic mercury is used in contact with solutions that contain mercury salts as the solid phase.

Mercury is used for separating gold and silver from their ores, for coating mirrors, in tanning, in batteries, for the frozen-mercury molding process, mercury-vapor motors, as a circulating medium in atomic reactors, and in its compounds for paint pigments and explosives.

The metal is marketed in steel flasks holding 75 lb (34 kg). The black *mercurous oxide*, Hg_2O , is used in skin ointments. *Mercuric chloride*, or *corrosive sublimate*, HgCl_2 , is an extremely poisonous, white, crystalline powder soluble in water and in alcohol, used as a wood preservative, as an insecticide and rat poison, in tanning, as a mordant, and as a caustic antiseptic in medicine. *Vermillion red*, one of the oldest paint pigments, is red *mercury sulfide*, HgS , made directly by heating mercury and sulfur. It is a brilliant, water-insoluble, red powder of specific gravity 8.1. Because of its expense, it is often mixed with other red pigments. *Mercurochrome* is a green crystalline powder that gives a deep-red solution in water and is used as an antiseptic. Mercury forms a vast number of compounds, all of which are poisonous and some of which are explosive. *Mercury 203* is radioactive. A mercury distillation process, developed by Lumalampan AB of Switzerland and called the *MRT System*, recovers mercury from fluorescent light bulbs, button batteries, amalgams, and electrical devices.

Mercury Seal

A gas-tight seal provided when a shaft enters equipment via a pool of mercury.

Mercury Switch

An electrical switch in which a rocking tubular vessel contains a limited amount of mercury that, at one rock position, covers the electrical contacts.

Mesh

(1) The number of screen openings per linear inch of screen; also called *mesh size*. (2) The screen number on the finest screen of a specified standard screen scale through which almost all of the particles of a powder sample will pass. See also *sieve analysis* and *sieve classification*. (3) Apart from its common meanings, in a metallurgical context, this term usually refers to the series of numbered sieves of decreasing mesh hole size used for grading powders.

Mesh Size

(1) The opening(s) or size of opening(s) in a designated sieve or screen, hence the approximate diameter of particles below which they will pass through and above which they will be retained on the screen. Mesh sizes are given as the number of wires per inch of standard screen construction, for example, Tyler or U.S.; these are translated by tables into equivalent particle diameters in inches (in.), millimeters (mm), or micrometers (μm). (2) The width of the aperture in a cloth or wire screen. See also *sieve analysis* and *sieve classification*.

Mesh-Belt Conveyor Furnace

A continuously operating furnace that uses a conveyor belt for the transport of the charge. Mesh-belt conveyor furnaces consist of a belt-driven table, a burn-off zone, a slow-cooling zone, a final-cooling zone, and a discharge table.

Mesophase

An intermediate phase in the formation of carbon from a pitch precursor. This is a liquid crystal phase in the form of microspheres, which upon prolonged heating above 400°C (750°F), coalesce, solidify, and form regions of extended order. Heating to above 2000°C (3630°F) leads to the formation of graphite structure.

Metal

(1) An imprecise term. Generally material showing most if not all of the following characteristics—crystalline with the atoms in a simple lattice with shared valence electrons, good strength, ductility and malleability, lustrous, and high electrical and thermal conductivities. (2) An opaque lustrous elemental chemical substance that is a good conductor of heat and electricity and, when polished, a good reflector of light. Most elemental metals are malleable and ductile and are, in general, denser than the other elemental substances. (3) As to structure, metals may be distinguished from nonmetals by their atomic binding and electron availability. Metallic atoms tend to lose electrons from the outer shells, the positive ions thus formed being held together by the electron gas produced by the separation. The ability of these “free electrons” to carry electric current, and the fact that this ability decreases as temperature increases, establishes a prime distinction of a metallic solid. (4) From a chemical viewpoint, an elemental substance whose hydroxide is alkaline. (5) An alloy.

Metal

A metal is a solid or liquid (molten), opaque material with a lustrous surface and good electrical and thermal conductivities. Solid metal is usually crystalline and ductile and can be permanently deformed by shear on crystal planes; permanent deformation is accompanied by an increase in strength (work hardening). Metallic properties are related to the arrangements of positively charged ions bonded through a surrounding field (sea) of free electrons that draw the ions into a close-packed crystalline structure with planes appropriate for slip. Liquids are nearly close-packed noncrystalline structures, with a thermal energy great enough to activate random, free movements of atoms.

The rapid developments of the metals industry since the late nineteenth century required an in-depth understanding of the fundamentals of metallurgy to improve metal properties and expand their usefulness.

Characteristics of Solids

The unique characteristics of the different classes of solids are directly related to the electron pattern and the types of bonds between the atoms of the solid. Atomic bonding is classified into two major categories: strong attraction (covalent, ionic, or metallic) and weaker, secondary bonding (van der Waals' or hydrogen bonding).

Directional Bonds

A covalent bond between two or more atoms is a negative charge directed in space and equivalent in magnitude to one or more electrons. As a consequence, at the lowest energy state, the corresponding bond is directional and usually strong, and considerable energy must be supplied to the material to free an electron from this bond or shift an ion from one fixed position to another. For covalent materials, bonding valence electrons require large energies to transport a current composed of many electrons through the aggregate atoms. Thus, electrical conductivity and thermal conductivity by electrons are low.

Metallic Bonding

In contrast to directional bonds, metallic bonds result from linking ions each having centro-symmetrical attraction to a surrounding atmosphere of the distributed charges of nearly free electrons. These electrons, usually valence electrons, have the same likelihood of being associated with any ion in the aggregate.

Crystal Structure

To visualize groups of atoms in an aggregate, the atoms are considered as spheres of the same radius.

This representation of metal atoms is reasonable since bonds originating from metal atom cores with the superimposition of the electron charges in the intervening space are manifested by a nearly spherically symmetrical attraction between the ions.

Among metals, the face-centered cubic crystalline structure is found in aluminum, nickel, copper, rhodium, palladium, silver, iridium, platinum, gold, and lead.

Because some metals display characteristics of other bonding types, they occur in other crystal structures primarily because of the interference of electrons at energy levels that are not centrally symmetric. All close-packed hexagonal metals belong to two categories that can be illustrated by packing elongated or compressed spheres.

An ideal hexagonal close-packed structure illustrates the hexagonal stacking of spheres, whereas spheres compressed in a direction perpendicular to a close-packed plane have an axial ratio less than

the ideal of 1.633. Examples are cobalt, rhenium, titanium, gadolinium, hafnium, and beryllium as well as lanthanum, cadmium, and zinc.

Other metals such as iron, titanium, tungsten, molybdenum, niobium, tantalum, potassium, sodium, vanadium, chromium, and zirconium (alkali and transition metals) are slightly less closely packed, with a body-centered cubic crystal structure that is 8.1% lower in packing density than face-centered cubic crystals. Furthermore, the equilibrium crystal structure for many metals is dependent on temperature and pressure. Consequently, a large number of elements are allotropic; that is, the element will appear as different crystal structures at various ranges of pressure-temperature conditions. Included in this group are calcium, titanium, manganese, iron, cobalt, yttrium, zirconium, tin, hafnium, thallium, polonium, thorium, and uranium.

Polycrystalline Metals

Common metallurgical production methods inevitably lead to solids made up of many small crystals separated by higher-energy boundaries containing nonlattice-positioned arrangement of atoms. The crystals in these polycrystalline metals are called grains, and the boundaries are grain boundaries. Since the grain boundaries interrupt periodicity of the lattice, they have a large effect on many of the physical and mechanical properties. They are origins (sources) and terminators (sinks) to all other defects, especially vacancies, solute atoms, and dislocations.

In an ideal polycrystalline arrangement composed of many randomly oriented grains, the anisotropic features of each grain are averaged, and the resulting metal solid would have isotropic properties. Actually, metal manufacturing processes such as casting and deformation forming (forging, rolling, and so forth) tend to develop grains with specific crystallographic directions distributed about certain directions that are distinctive of the forming process and the geometry of the bulk product. This nonrandom arrangement of grains, called preferred orientation, contributes to anisotropy of properties in the final polycrystalline product.

Metal Alloys

An alloy has metallic features and is composed of two or more chemical elements. Macroscopically, it appears homogeneous, but microscopically various thermodynamically stable arrangements of the chemical elements are possible, depending on the characteristics of the components.

Metal Casting

Metal casting involves the introduction of molten metal into a cavity or mold where, upon solidification, it becomes an object whose shape is determined by mold configuration. Casting offers several advantages over other methods of metal forming. It is adaptable to intricate shapes, to extremely large pieces, and to mass production; it can provide parts with uniform physical and mechanical properties throughout; and, depending on the particular material being cast, the design of the part, and the quantity being produced, its economic advantages can surpass other processes.

Categories

Two broad categories of metal-casting processes exist: ingot casting (which includes continuous casting) and casting to shape.

M

Ingots are produced by pouring molten metal into permanent or reusable molds. Following solidification, these ingots (or bars, slabs, or billets, as the case may be) are then further processed mechanically into many new shapes. Casting to shape involves pouring molten metal into molds in which the cavity provides the final useful shape, followed only by machining or welding for the specific application. Another mode of metal casting, zero gravity casting, has been developed for processing in a space station.

Ingot Casting

Ingots make up the majority of all metal castings and are separated into three categories: static cast ingots, semi-continuous or direct-chill cast ingots, and continuous cast ingots.

Static Cast Ingots: Static ingot casting simply involves pouring molten metal into a permanent mold. After solidification, the ingot is withdrawn from the mold and the mold can be reused. This method is used to produce millions of tons of steel annually.

Semicontinuous Cast Ingots: A semicontinuous casting process is employed in the aluminum industry to produce most of the cast alloys from which rod, sheet, strip, and plate configurations are made. In this process, molten aluminum is transferred to a water-cooled permanent mold that has a movable base mounted on a long piston. After solidification has progressed from the mold surface so that a solid “skin” is formed, the piston is moved down, and more metal continues to fill the reservoir. However, technological advances have allowed major aluminum alloy producers to replace the metal mold (at least in part) by an electromagnetic field so that molten metal touches the metal mold only briefly, thereby making a product with a much smoother finish than that produced conventionally.

Continuous Cast Ingots: Continuous casting provides a major source of cast material in the steel and copper industry and is growing rapidly in the aluminum industry. In this process, molten metal is delivered to a permanent mold, and the casting begins much in the same way as in semicontinuous casting. However, instead of the process ceasing after a certain length of time, the solidified ingot is continually sheared or cut into lengths and removed during casting. Thus, the process is continuous, with the solidified bar or strip being removed as rapidly as it is cast. The method has many economic advantages over the more conventional casting techniques; as a result, all modern steel mills produce continuous cast products.

Cast to Shape

Casting to shape is generally classified according to the molding process, molding material, or method of feeding the mold. There are four basic types of these casting processes: sand, permanent-mold, die, and centrifugal.

Sand Casting: This is the traditional method that still produces the largest volume of cast-to-shape pieces. It utilizes a mixture of sand grains, water, clay, and other materials to make high-quality molds for use with molten metal. Other casting processes that utilize sands as a basic component are the shell, carbon dioxide, investment casting, ceramic molding, and plaster molding processes. In addition, there are a large number of chemically bonded sands that are becoming increasingly important.

Permanent Mold Casting: Many high-quality castings are obtained by pouring molten metal into a mold made of cast iron, steel, or bronze. Semipermanent mold materials such as aluminum, silicon carbide, and graphite may also be used. The mold cavity and the gating system are machined to the desired dimensions after the mold is cast; the smooth surface from machining thus gives a good surface finish and dimensional accuracy to the casting.

Die Casting: A further development of the permanent molding process is die casting. Molten metal is forced into a die cavity under pressures of 0.7–700 MPa. Two basic types of die-casting machines are hot chamber and cold chamber. In the hot-chamber machine, a portion of the molten metal is forced into the cavity at pressures up to about 14 MPa. The process is used for casting low-melting point alloys such as lead, zinc, and tin. In the cold-chamber process, the molten metal is ladled into the injection cylinder and forced into the cavity under pressures that are about 10 times those in the hot-chamber process. High-melting-point alloys such as aluminum-, magnesium-, and copper-base alloys are used in this process. Die casting has the advantages of high production rates, high quality and strength, surface finish on the order of 1.0–2.5 $\mu\text{m rms}$, and close tolerances with thin sections. Rheocasting is the casting of a mixture of solid and liquid. In this process, the alloy to be cast is melted and then allowed to cool until it is about 50% solid and 50% liquid. Vigorous stirring promotes liquidlike properties of this mixture so that it can be injected in a die-casting operation. A major advantage of this type of casting is expected to be much reduced die erosion due to the lower casting temperatures.

Centrifugal Casting: Inertial forces of rotation distribute molten metal into the mold cavities during centrifugal casting, of which there are three categories: true centrifugal casting, semi-centrifugal casting, and centrifuging. The first two processes produce hollow cylindrical shapes and parts with rotational symmetry, respectively. In the third process, the mold cavities are spun at a certain radius from the axis of rotation; the centrifugal force thus increases the pressure in the mold cavity.

Evaporative Cooling

This is another casting process that utilizes sand as a basic component. However, it is unique in that the casting shape is not defined by molding the sand. Rather, a polystyrene foam pattern or replica is formed into the shape of the component to be cast and determines the size and shape of the final casting.

The evaporative casting process is compatible with bronze, steel, aluminum, and iron castings. In general, microstructural characteristics of castings made by the evaporative casting process tend to be the same as those of castings made by conventional sand casting processes.

The major advantages of the evaporative casting process are reduced costs and greater overall flexibility. Cost savings occur both in lower investment costs and lower cost to make a casting. The lower investment costs come about because the equipment to make polystyrene foam replicas is less expensive than the equipment to make conventional sand molds and cores. Also, the polystyrene molding equipment operates at higher speeds. Finally, the tooling to make polystyrene foam replicas is also less expensive and has a longer life than tooling for conventional sand molds and cores. The costs for making a single casting by the evaporative casting process are lower because this process does not require cores and allows for

easy reuse of the casting sand (no resins are added to the sand). Also, the casting made by this process is easier to clean than a conventional sand casting because these are no fins and parting lines that need to be ground down.

Zero-Gravity Casting

Another mode of metal casting, zero-gravity casting, has come of age with the advent of space stations containing laboratory equipment with metal-processing capabilities. In the absence of gravity, the concept of melting and casting is drastically changed. The disadvantages of Earth-based processing that appear to be diminished or eliminated by processing under conditions of weightlessness are thermal and solutal convection and sedimentation, contamination of and contact with the container during processing, and hydrostatic pressure effects and deformation at high temperatures. Thus, there appears to be potential for processing liquid metals at zero gravity. However, commercial production is expected to be limited initially to small quantities of high-cost materials whose solidification characteristics are greatly improved by the lack of gravity. Semi-conductor materials are thought to be excellent candidates for initial development efforts.

Principles and Practice

Successful operation of any metal-casting process requires careful consideration of mold design and metallurgical factors. These include design consideration, heating systems, riser design, ease of pattern extraction, machining considerations, and, finally, metallurgical considerations, where the relationship between the processing history and the solidification event for a part that is cast to shape.

Applications

Ferrous alloys, steels, and cast irons constitute the largest volume of metals cast. Aluminum-, copper-, zinc-, titanium-, cobalt-, and nickel-base alloys are also cast into many forms, but in much smaller quantity than iron and steel.

Aluminum alloy castings have advantages such as resistance to corrosion, high electrical conductivity, ease of machining, and architectural and decorative uses. Magnesium alloy castings have the lowest density of all commercial casting alloys. Copper alloy castings, although costly, have advantages such as corrosion resistance, high thermal and electrical conductivities, and wear properties suitable for antifriction bearing materials. In steel, castings have more uniform (isotropic) properties than the same component obtained by mechanical working. On the other hand, because of high temperatures required, casting of steel is relatively expensive and requires considerable knowledge and experience. Cast irons, which constitute the largest quantity of all metals cast to shape, and properties such as hardness, wear resistance, machinability, and corrosion resistance. Gray iron castings are commonly produced for their low cost, machinability, good damping capacity, and uniformity. Nodular cast irons have significantly higher strengths than gray irons but are more costly and not as machinable. There is an intermediate grade of cast-iron called CG (compacted graphite) iron that shares the best properties of both gray and nodular irons.

Metal Coatings

These are thin films of material bonded to metals to add specific surface properties, such as corrosion or oxidation resistance, color, attractive appearance, wear resistance, optical properties, electrical resistance, or thermal protection. In all cases, proper surface

preparation is essential to effective bonding between coating and basis metal so that coated metals can function as duplex materials. The various methods of applying either metallic coatings (hot dip, electroplating, spray, cementation, vapor deposition, cladding, and immersion) or nonmetallic coatings, such as vitreous enamel and ceramics, and the conversion of surfaces to suitable reaction-product coatings.

Hot-Dip

Low-melting metals provide inexpensive protection to the surfaces of a variety of steel articles. To form hot-dip coatings, thoroughly cleaned work is immersed in a molten bath of the coating metal. The coating consists of a thin alloy layer together with a relatively pure coating metal that adheres to the work as it is withdrawn from the bath. Sheet, strip, and wire are processed on a continuous basis at speeds of several hundred feet per minute. On the other hand, hardware and holloware are handled individually or in batches.

Galvanized steel, that is, steel hot-dipped in zinc, is used for roofing, structural shapes, hardware, sheet, strip, and wire products. Hot-dipped tinplate is now largely supplanted by electroplated tinplate for tin cans. Terne plate, with coatings up to 20 μm , is used for roofing, chemical cabinets, and gasoline tanks. Hot-dip aluminum-coated (aluminized) steel with coatings up to 10 μm thick are used for oil refinery equipment and furnace and appliance parts where protection at temperatures up to 538°C is required.

Sprayed

A particular advantage of sprayed coatings is that they can be applied with portable equipment. The technique permits the coating of assembled steel structures to obtain corrosion resistance, the building up of worn machine parts for rejuvenation, and the application of highly refractory coatings with melting points in excess of 1650°C.

Nearly any metal or refractory compound can be applied by spraying. Coating material in the form of wire or powder is fed through a specially designed gun, where it is melted and subjected to a high-velocity gas blast that propels the atomized particles against the surface to be coated.

Coatings such as zinc and aluminum are applied with a gun that provides heat by burning acetylene, propane, or hydrogen in oxygen. Highly refractory coating materials, such as oxides, carbides, and nitrides, can be applied by plasma-arc spraying. In this process, temperatures of 12,000°C or more may be produced by partially ionizing a gas (nitrogen or argon) in an electric arc and passing the gas through a small orifice to produce a jet of hot gas moving at high velocity. Another variation for applying refractory coatings is detonation-flame plating. In this process, a mixture of oxygen and gas-suspended fine particles is fired four times per second by a timed spark.

Sprayed zinc or aluminum coatings up to 250 μm are used to protect towers, tanks, and bridges. Such coatings are normally sealed with an organic resin to enhance protection.

Sprayed refractory coatings have been developed for the high temperatures experienced in aerospace applications. They are also used for wear resistance, heat resistance, and electrical insulation.

Cementation

There are surface alloys formed by diffusion of the coating metal into the base metal, producing little dimensional change. Parts are heated in contact with powder coating material that diffuses into the

M

surface to form an alloy coating, whose thickness depends on the time and the temperature of treatment. A zinc alloy coating of 25 μm is formed on steel in 2–3 h at 375°C. A chromium alloy (chromized) coating of 100 μm is formed in 1 h at 1000°C.

Chromized coatings on steel protect aircraft parts and combustion equipment. Sherardized (zinc–iron alloy) coatings are used in threaded parts and castings. Calorized (aluminum–iron alloy) coatings protect chemical equipment and furnace parts. Diffusion coatings are used to provide oxidation resistance to refractory metals, such as molybdenum and tungsten, in aerospace applications where reentry temperatures may exceed 1650°C. In addition to the pack process described earlier, such coatings may be applied in a fluidized bed. In forming disilicide coatings on molybdenum, the bed consists of silicon particles suspended in a stream of heated argon flowing at 0.15 m/s, to which a small amount of iodine is added. The hot gases react with the silicon to form SiI_4 , which in turn reacts with the molybdenum to form MoSi_2 .

Vapor Deposition

A thin specular coating is formed on metals, plastics, paper, glass, and even fabrics. Coatings form by condensation of metal vapor originating from molten metal, from high-voltage (500–2000 V) discharge between electrodes (cathode sputtering), or from chemical means such as hydrogen reduction or thermal decomposition (gas plating) of metal halides. Vacuums up to 10^{-4} Pa often are required.

Aluminum coatings of 0.125 μm are formed on zinc, steel, costume jewelry, plastics, and optical reflectors. Chemical methods can form relatively thick coatings, up to 250 μm .

Immersion

Either by direct chemical displacement or, for thicker coatings, by chemical reduction (electroless coating), metal ions plate out of solution onto the workpiece.

Tin coatings are displaced onto brass and steel notions and on aluminum–alloy pistons as an aid during the breaking-in period. Displacement nickel coatings of 1.25 μm are formed on steel articles. Electroless nickel, involving the reduction of a nickel salt to metallic nickel (actually a nickel–phosphorus alloy), permits the formation of relatively thick uniform coatings up to 250 μm on parts with recessed or hidden surfaces difficult to reach by electroplating.

Vitreous Enamel

Glassy but noncrystalline coatings for attractive durable service in chemical, atmospheric, or moderately high-temperature environments are provided by enamel or porcelain coating.

Dry enameling is used for castings, such as bathtubs. The casting is heated to a high temperature, and then dry enamel powder is sprinkled over the surface, where it fuses.

Firing temperatures for conventional enameling of iron or steel range up to 870°C. Low-temperature enamels have been developed, permitting the enameling of aluminum and magnesium.

Coatings of 75–500 μm are used for kitchenware, bathroom fixtures, highway signs, and water heaters. Vitreous coatings with crystalline refractory additives protect stainless steel equipment at temperatures up to 950°C.

Ceramic

Essentially crystalline, ceramic coatings are used for high-temperature protection above 1100°C. The coatings may be formed

by spraying refractory material such as aluminum oxide or zirconium oxide, or by the cementation processes for coatings of intermetallic compounds such as molybdenum disilicide. Cermets are intimate mixtures of ceramic and metal, such as zirconium boride particles, dispersed throughout an electroplated coating of chromium.

Surface Conversion

An insulating barrier of low solubility is formed on steel, zinc, aluminum, or magnesium without electric current. The article to be coated is either immersed in or sprayed with an aqueous solution, which converts the surface into a phosphate, an oxide, or a chromate. Modern solutions react so rapidly that sheet and strip materials can be treated on continuous lines.

Phosphate coatings, equivalent to 1–4 g/m^2 , are applied to bare or galvanized steel and to zinc-base die castings as preparation for painting. The coating enhances paint adhesion and prevents underfilm corrosion. Phosphate coatings, containing up to 40 g/m^2 (lubricated), serve as an aid in deep-drawing steel and in other friction-producing processes or applications. Iridescent chromate coatings on zinc-coated steel improve appearance and reduce zinc corrosion. Chromate, phosphate, and oxide coatings on aluminum or magnesium are used to prepare the surface before painting.

Anodic

Coatings of protective oxide may be formed on aluminum or magnesium by making them the anode in an electrolytic cell. Anodized coatings on aluminum up to 75 μm thick are formed in sulfuric acid to form a porous oxide that may be sealed in boiling water or steam to provide a clear, abrasion-resistant, protective coating.

Such coatings are used widely on aluminum furniture, automobile trim, and architectural shapes. Thin, nonporous, electrically resistant coatings are formed on aluminum in a boric acid bath in the production of electrolytic capacitors. Anodized coatings on magnesium are thicker (up to 75 μm) and harder than those formed by chemical conversion. Anodic coatings of 7.5 μm thick are often used as a paint base.

Powder

The term *powder coatings* refers to a process whereby organic polymers such as acrylic, polyester, and epoxies are applied to substrates for protection and beautification. It is essentially an industrial painting process that uses a powdered version (25–50 μm particle size) of the resin rather than the solvent solution represented by industrial baking enamels.

In the widest type of commercial usage, these powders are applied to electrically grounded substrates by means of an electrostatic spray gun. In these guns, high-voltage (60–100 kV), low-amperage charges are applied to the powders. The powder particles are attracted to and adhere to the substrate until it can be transported to an oven, where the powder particles melt, coalesce, flow, and form a smooth coating. Typical baking temperatures are 90°C for 20 min.

Coatings can be applied at thicknesses ranging from 25 to 250 μm , depending upon use requirements.

Although electrostatic spray is the principal method of commercial application, other techniques exist, including fluidized-bed coating, where a preheated part is immersed into an aerated bed of powder particles, and electrostatic fluidized bed, where a substrate is passed through an “electrified” cloud of the powder.

Powder coating uses no organic solvent, and the oversprayed material can be recaptured and reused. Thus, there are several notable advantages over conventional industrial solvent-based painting:

1. There are no hydrocarbon baking byproducts, and the process is environmentally acceptable.
2. Material conservation and economics are optimized because of the recycling of oversprayed material.
3. Powders are easy to apply and readily lend themselves to automation.

A wide variety of parts are finished with powder coatings. Outdoor lawn and patio furniture coated in this process display good weathering and abuse resistance. Powder-coated electrical transformers are insulated electrically and provided with corrosion protection. Powder coatings have also been developed for finishing major appliances and for automobile coatings. Also, laundry tops and lids have displayed excellent detergent resistance where organic powder coatings have replaced porcelain finishes.

Metal-Cored Electrode

A composite filler metal welding electrode consisting of a metal tube or other hollow configuration containing alloying ingredients. Minor amounts of ingredients facilitate arc stabilization and fluxing of oxides. External shielding gas may or may not be used.

Metal Dusting

Accelerated deterioration of metals in carbonaceous gases at elevated temperatures to form a dust-like corrosion product.

Metal Electrode

An electrode used in arc welding or cutting that consists of a metal wire or rod that is either bare or covered with a suitable covering or coating.

Metal Fatigue

The same as fatigue. The shorter term is usually used by metallurgists.

Metal Foams

Metal foams are metallic cellular materials that have a high porosity fraction, typically ranging from 40 to 90 vol%. Because of their high stiffness and low specific weight, cellular materials are applied in construction: packaging, insulation, noise and vibration damping, and filtering. They are considered by many to be a new class of engineering material.

Typical foaming processes include casting, powder pressing, metallic deposition, and sputter deposition. Metal foams can be fabricated in a variety of different ways, and many attempts have been made in the past to develop good foam structure. However, the choice frequently seems to be between high cost and poor quality.

A new powder method allows for direct net-shape fabrication of phone parts with a relatively homogeneous pore structure. Metallic foams fabricated by this approach exhibit a closed-cell microstructure with a higher mechanical strength than open-cell foams. This type of microstructure is particularly appropriate for applications requiring reduced weight and energy-absorption capabilities.

The powder-metallurgy production method makes it possible to build metallic foam parts that have complex geometry. Sandwich structures composed of a porous metallic foam core and metallic face sheets can also be produced, with options exploiting combined materials and shapes. These foams enlarge the application range of cellular materials because of their excellent physical and mechanical properties, as well as their relative recyclability.

Processing

The process consists of mixing metal powders (either prealloyed metal powders or powder blends) with a small amount of foaming agent. When the agent is a metal hydride, a content of less than 1% is generally sufficient. After the foaming agent is uniformly distributed within the matrix powders, the mixture is compacted into a dense, semifinished product with no residual open porosity. Typical compaction methods include uniaxial pressing, extrusion, and powder rolling. The foamable material may be further shaped through subsequent metal-working processes such as rolling, swaging, or extrusion.

Potential Applications

The following is a list of applications currently being investigated:

- *Automotive industry:* Light, stiff structures made of aluminum foam and foam sandwich panels could help to reduce weight and increase stiffness. Examples are hoods, trunk lids, and sliding roofs. With regard to energy absorption, it is possible to engineer controlled deformation into the crash zone of cars and trains with maximum impact-energy dissipation. Possible applications include elements for side and front impact protection. In general, foam filling leads to higher deformation forces when profiles are bent and to higher energy absorption when profiles are axially crushed. Potential applications include bumpers, underside protection of trucks, A- and B-pillars, and other elements subjected to large deformation.
- *Aerospace industry:* Metal foam sandwich panels offer good potential to replace expensive honeycomb structures in the aerospace industry. The attributes of metal foams include the isotropy of the foam material and fire retardation to maintain the integrity of the structure. Roll cladding for direct metallic bonding can eliminate the need for adhesive bonding in the sandwich panels.
- *Building industry:* Many construction applications require light, stiff, and fire-resistant elements, or supports for such elements. Foam sandwich panels could help to reduce the energy consumption for elevators by trimming the deck weight. Combining energy absorption and high specific stiffness, the foamed sandwich panels may be a good candidate for these applications. Another application of the metal foams is to fasten plugs into concrete walls. To fill the gap between the plugs and the wall, the foamable materials can be inserted into the gap and locally heated. The foamable material will expand and fill the space between the plugs and the concrete wall, provided that the resultant foam density is high enough.
- *Further applications:* Additional applications can capitalize on the properties of foams made from other metals. For example, lead and nickel foams may be suitable for batteries, and gold or silver foams may be applicable in art and jewelry. Furthermore, open-cell foams can be fabricated

by modifying the process scheme. This material would be excellent for several applications, such as heat exchangers, filters, and catalyst carriers. Foaming of high-temperature alloys such as nickel and titanium will also help expand the application range, especially for aerospace and biomedical components.

Metal Forming

Metal forming is any manufacturing process by which parts or components are fabricated from metal stock. In the specific technical sense, metal forming involves changing the shape of a piece of metal. In general terms, however, it may be classified roughly into five categories: (1) mechanical working, such as forging, extrusion, rolling, drawing, and various sheet-forming processes; (2) casting; (3) powder and fiber metal forming; (4) electroforming; and (5) joining processes. The selection of a process, or combination of processes, requires a knowledge of all possible methods of producing the part if a serviceable part is to be produced at the lowest overall cost.

Metal Hydrides

A metal hydride is a compound in which hydrogen is bonded chemically to a metal or metalloid element. The compounds are classified generally as ionic, transition metal, and covalent hydrides.

Ionic Hydrides

The most reactive metals (alkali and alkaline earth metals, with the exception of magnesium and beryllium) combine directly on heating with hydrogen gas at a pressure of 10^2 kPa. Magnesium reacts at elevated hydrogen pressure.

Transition Metal Hydrides

This group of compounds is less well understood than the ionic and covalent hydrides. When lanthanum is heated in hydrogen, the gas is readily taken up, forming first a material whose composition is approximately $\text{LaH}_{1.86}$ (the “dihydride” phase) and finally LaH_3 .

The ionic hydrides, such as NaH , exhibit much more limited non-stoichiometry. When sodium is converted to pure NaH , all electrons in the conduction band are consumed and the product is white and insulating.

Copper hydride, CuH , is unique in that it is the only hydride that can be precipitated from aqueous solution.

Titanium, zirconium, vanadium, and niobium all react with hydrogen, forming dihydrides at the limiting compositions. The materials are conducting at all compositions.

Common metals such as steel and copper dissolve small quantities of hydrogen at elevated temperatures. On cooling, the gas comes out of solution and results in severe degradation of the mechanical properties of the metals. This is called hydrogen embrittlement and can be prevented by degassing the metal while it is still molten.

A number of alloys or intermediate compounds are known that react with hydrogen and form ternary hydrides. Examples are LaNi_5H_6 , Mg_2NiH_4 , AlTh_2H_2 , and CaAg_2H .

Covalent Hydrides

Most evidence indicates that in ionic and metallic hydrides, an electronic pair is associated primarily with the hydrogen as H^- , while in covalent hydrides, the electron pair is shared between the hydrogen

atom and an atom of another element. In these compounds, hydrogen is considerably smaller (radius 0.03 nm) than in the ionic hydrides. Covalent hydrides usually consist of small molecules, in which case they are gases (SiH_4 and SbH_3), but some form high polymers, in which case they are nonvolatile solids (AlH_3 and ZnH_2). All tend to decompose irreversibly rather easily on heating. Covalent hydrides are generally synthesized indirectly, not from direct combination of the elements. Gaseous hydrides such as SiH_4 , PH_3 , and AsH_3 can be generated by heating a solid mixture of the corresponding oxide and LiAlH_4 .

Metal Inert-Gas Welding (MIG)

Gas metal arc welding using an inert gas such as argon as a shielding gas.

Metal Inject Ion Molding

Injection molding is one of the most productive techniques for shaping materials. Until recently, injection molding was restricted to thermoplastic polymers (polymers that melt on heating). However, metals have property advantages over polymers. They are stronger, stiffer, are electrically and thermally conductive, can be magnetic, and are more wear and heat resistant. The concept of metal injection molding (MIM) combines metal powders in a thermoplastic binder to allow shaping of complex objects in the high-productivity manufacturing setting associated with injection molding. After shaping, the metal powders are sintered to densities close to those listed in handbooks; that is, they have very few pores. Accordingly, the process delivers materials with metallic properties in an efficient manner.

MIM, and the related process of ceramic injection molding, is a derivative of powder metallurgy. Metal powders can be shaped in a semifluid state (powders that are poured into containers take on the shape of the container), but after heating to high temperatures, the particles bond into a strong, coherent mass. In ceramics, this is analogous to the manufacture of clay pottery, where shaping occurs with a water-clay system at the potter's wheel, but after kiln firing, the structure is strong and rigid.

MIM is a process in which metal in a powdered form is combined with a polymer binder to produce a homogeneous mixture known as feedstock. The feedstock is processed in a manner similar to plastic injection molding, except that parts are designed slightly larger to account for shrinkage during the final sintering step. The molded part is called the “green” part.

Once molded, three methods are available to remove the binder from the green parts: solvent, thermal, and catalytic debinding. Differences in these methods affect the outcome of the product. The debinding phase can be the most time-consuming aspect of the process. After debinding, parts (known as “brown” parts) are sintered—a process in which the components are exposed to heat over an extended period.

Applications

MIM is applied in the production of high-performance components that have complex shapes. The most successful applications involve components that have complex shapes and also must be inexpensive to produce while providing high relative performance. Generally, MIM can be used for all shapes that can be formed by plastic injection molding, especially for very small complex geometries.

Many applications have been developed for MIM. They include components for use in diverse fields ranging from surgical tools to microelectronic packaging. Recently, automotive components such as sensor parts in the air-bag actuator mechanism have moved into production. The technology has been extended to utilize a wide range of materials, including steels, stainless steels, nickel, copper, cobalt alloys, tungsten alloys, niobium alloys, nickel-base superalloys, and intermetallics. Additionally, most ceramics can be processed in the same manner; these include silica, alumina, zirconia, or silicon nitride, silicon carbide, aluminum nitride, cemented carbides, and various electronic ceramics.

Although MIM is generally viable for all shapes that can be formed by plastic injection molding, it is not cost competitive for relatively simple or asymmetric geometries. Large components require larger molding and sintering devices that are more difficult to control. Accordingly, MIM is largely applied to smaller shapes with masses below 100 g.

As the engineering community better appreciates its favorable attributes, MIM applications will grow. Although the current industry is relatively small, the anticipated growth is impressive. One area of keen interest is in the processing of titanium alloys for biomedical applications. Another is in the co-molding of different materials, that is, forming part of a component from one material and then another portion from a second material. This option has merit for forming corrosion barriers, wear surfaces, and electrical interconnections in ceramics. Other major growth areas include high-performance magnets, technical ceramics, materials associated with heat dissipation electronic circuits, hard materials, ultrahigh-strength metals, and biocompatible materials.

Metal Leaf

Thin metal sheet, usually thinner than foil, and traditionally produced by beating rather than by rolling.

Metal Penetration

A surface condition in metal castings in which metal or metal oxides have filled voids between sand grains without displacing them.

Metal Powder Cutting

A technique that supplements an oxyfuel torch with a stream of iron or blended iron–aluminum powder to facilitate flame cutting of difficult-to-cut materials. The powdered material propagates and accelerates the oxidation reaction, as well as the melting and spalling action of the materials to be cut.

Metal Powders

By definition, a metal powder is an aggregate of discrete metal particles that are usually in the size range of 1–1000 μm .

The metal powders in common use are lead–tin alloys for solders; iron-, nickel-, and cobalt-base alloys for hard facing; copper-, silver-, and nickel-base alloys for brazing; aluminum, bronze, and stainless steel for paint pigments; magnesium for pyrotechnics; iron for welding rods, torch cutting and scarfing, and metal powder parts; copper for metal-powder parts; and carbide for tools. Used in smaller quantities are iron powders for radio and television tuning cores; nickel–iron and silicon–iron alloy powders for other soft magnetic parts; aluminum, iron, nickel, and cobalt powders for small permanent magnets in the “Alnico” series; nickel and cobalt

powders as binders in the production of carbide tools and alloy and stainless steel powders for high-strength and special property parts.

Of these uses, the fabrication of structural parts or machinery components accounts for the largest single use of metal powders and competes with such other metal-forming methods as machining, casting, stamping, and forging. The powder-metallurgy technique may be selected by the designer as the best way to make a particular part for one of several reasons:

1. The process is ideal for mass-producing machine components at low unit cost.
2. Residual porosity can be controlled to provide long-wearing qualities through the self-lubricating feature of the “oil-less” sleeve bearing.
3. Metal combinations are possible through powder metallurgy that cannot be melted.
4. Powder-metallurgy techniques provide the only practical method of forming high-melting point metals.

The good surface finish and close dimensional tolerances possible are additional reasons why the designer may specify metal powder parts.

Although most metal powder parts are made from iron, copper, or mixtures of these primary powders with or without graphite additions, many other powders are used to develop special properties like high strength, magnetic or electrical properties, corrosion resistance, or oxidation resistance. The special powders include brass, bronze, alloy steels, stainless steel, and various nickel-base alloys. Many of the special powders are also employed in the production of metal filters.

Production Methods

Electrolytic

These methods are used to make most of the copper powder used for metal powder parts and a special, high-purity iron powder often used for making-dense iron powder parts.

Atomization

This is a molten metal production method applied to a wide range of powders including aluminum, magnesium, brass, bronze, lead, tin, nickel–silver, and stainless and low-alloy steels. Other more complex iron-, nickel-, and cobalt-base alloys are also made by atomization.

Metal Shadowing

The enhancement of contrast in a microscope by vacuum depositing a dense metal onto the specimen at an angle generally not perpendicular to the surface of the specimen. See also *shadowing*.

Metal Spraying

Any process for coating a surface by spraying it with a molten metal as small droplets. The flattened droplets only mechanically attached as there is insufficient time for diffusion to develop a stronger bond. See *thermal spraying* and *flame spraying*.

Metal Stitching

A mechanical technique for repairing cracks, for example, pairs of holes jig drilled on the two sides of a crack. The ligament between the pairs is then slit and “dumbbells” inserted. The dumbbells can

M

be a more complex shape, and they may be of a material matching the parent or they may be of a lower expansion material to provide a crack closure effect if the component is heated. If a pressure tight repair is required, a further hole is drilled on the line of the crack. This hole is tapped (i.e., threaded) and filled with a threaded plug. This is repeated along the crack with each plug slightly overlapping its predecessor and the dumbbells. The technique can never restore full strength, and it is usually confined to low ductility fractures, but it can be performed on-site and it does not require heating.

Metal Transfer (in Welding)

The manner in which metal is transferred across an electric arc from a consumable electrode to the weld pool. The term is particularly aimed at metal inert gas welding (MIG). High current cause spray transfer in which individual droplets, not greater in diameter than the electrode diameter, are projected across the arc gap. Lower currents cause globular transfer in which the molten metal accumulates at the electrode tip until eventually a droplet appreciably larger in diameter than the electrode is projected across the gap. The lower currents result in dip transfer in which an arc is initiated in the steadily advancing electrode dips into the weld pool causing a short circuit. The electrical surge melts a portion of the tip that detaches to enter the weld pool. The arc re-strikes, and the process repeats.

Metal(lic) Active Gas Welding (MAG)

Welding in which the electric arc is struck between the component being welded and a continuously fed consumable filler wire and the weld zone is shielded by a gas that is active rather than inert during the welding operation.

Metal Arc Cutting

Any of a group of arc cutting processes that sever metals by melting them with the heat of an arc between a metal electrode and the base metal. See also *shielded metal arc cutting* and *gas metal arc cutting*.

Metal Arc Welding

Any of a group of arc welding processes in which metals are fused together using the heat of an arc between a metal electrode and the work. Use of the specific process name is preferred.

Metal–Matrix Composites

A MMC is a material in which a continuous metallic phase (the matrix) is combined with another phase (the reinforcement) that constitutes a few percent to around 50% of the total volume of the material. In the strictest sense, MMC materials are not produced by conventional alloying. This feature differentiates most MMCs from any other multiphase metallic materials, such as pearlitic steels or hypereutectic aluminum–silicon alloys.

The particular benefits exhibited by MMCs, such as lower density, increased specific strength and stiffness, increased high-temperature performance limits, and improved wear-abrasion resistance, are dependent on the properties of the matrix alloy and of the reinforcing phase. The selection of the matrix is empirically based, using readily available alloys, and the major consideration is the nature of the reinforcing phase.

Matrices and Reinforcements

A large variety of MMC materials exist. The reinforcing phase can be fibrous, platelike, or equiaxed (having equal dimensions in all directions), and its size can also vary widely, from about 0.1 to more than 100 μm . Matrices based on most engineering metals have been explored, including aluminum, magnesium, zinc, copper, titanium, nickel, cobalt, iron, and various aluminides. This wide variety of systems has led to an equally wide spectrum of properties for these materials and of processing methods used for their fabrication.

Reinforcements used in MMCs fall in five categories: continuous fibers, short fibers, whiskers, equiaxed particles, and interconnected networks.

Continuous Fibers

Several continuous fibers or filaments are used in MMCs. Their elastic moduli vary significantly, depending on the nature of the fiber and its fabrication process. For example, silica–alumina spinels and micro crystalline or amorphous polycarbosilane-derived fibers possess significantly lower elastic moduli than do pure alumina or crystalline β -silicon carbide produced by chemical vapor deposition. Carbon fiber strength and modulus also vary significantly with processing, depending on the level of graphitization of the microstructure.

Short Fibers

Short fibers are less expensive, especially when they are mass-produced for other applications such as high-temperature thermal insulation. Their physical properties can be similar to those of continuous fibers; however, their reinforcing efficiency in the matrix is also far lower. Short fibers used in engineering practice include chopped carbon fibers and alumina–silica fibers.

Whiskers

Whiskers are single-crystal short fibers, produced to feature highly desirable mechanical properties due to lack of microstructural defects. Whiskers have typically been made of silicon carbide, and they are often priced far higher than short fibers. The high price and toxicity of most whiskers have prevented their application in engineering practice.

Single-crystal whiskers, because of the absence of grain boundary defects, offer much higher tensile strength than other types of discontinuous reinforcements, and thus they are preferred for certain applications of discontinuously reinforced MMCs. The whiskers can be aligned to a preferred orientation by conventional metallurgical processes; higher directional strengths can be achieved in finished components where fabrication is by extrusion, rolling, forging, or superplastic forming. Whiskers tend to produce anisotropic properties due to their alignment during processing, whereas particular materials usually produce essentially isotropic properties.

Equiaxed Particles

Equiaxed particles of several ceramics, including those containing silicon carbide, aluminum oxide, boron carbide, and tungsten carbide, do not provide the possibility for preferential strengthening of the matrix along selected directions; however, their price is low and their combination with the metal is relatively easier. These reinforcements are, therefore, used in many MMC systems, including mass-produced aluminum–matrix composites.

Interconnected Cellular Networks

These can be produced by several methods, such as by chemical vapor deposition of ceramic onto a pyrolyzable polymer foam or by conversion of a preceramic polymer foam prior to infiltration with the molten matrix. Alternatively, some processing techniques for in-place MMCs, including directional oxidation of aluminum melts, produce interconnected reinforcing networks.

Microstructures

The microstructure of a MMC comprises the structure of matrix and reinforcement, that is, the interface and the distribution of the reinforcement within the matrix.

Composite Properties

Composite properties depend first and foremost on the nature of the composite; however, certain detailed microstructural features of the composite can exert a significant influence on its behavior.

Physical properties of the metal, which can be significantly altered by addition of a reinforcement, are chiefly dependent on the reinforcement distribution. A good example is aluminum–silicon carbide composites, for which the presence of the ceramic increases substantially the elastic modulus of the metal without greatly affecting its density. Elastic moduli for 6061 aluminum–matrix composites reinforced with discrete silicon carbide particles or whiskers have been calculated by using the rule of mixtures for the same matrix reinforced with two types of commercial continuous silicon carbide fibers. As a result, several general facts become apparent. First, modulus improvements are significant, even with equiaxed silicon carbide particles, which are far less expensive than fibers or whiskers. However, the level of improvement depends on the shape and alignment of the silicon carbide. Also, it depends on the processing of the reinforcement; for the same reinforcement shape (continuous fibers), microcrystalline polycarbosilane-derived silicon carbide fibers yield much lower improvements than do crystalline β -silicon carbide fibers. These features, which influence reinforcement shape, orientation, and processing of modules, are quite general; they are also observed, for example, in MMCs reinforced with aluminum oxide or carbon.

Other properties, such as the strength of MMCs, depend in a much more complex manner on composite microstructure. The strength of a fiber-reinforced composite, for example, is determined by fracture processes, themselves governed by a combination of microstructural phenomena and features. These include plastic deformation of the matrix, the presence of brittle phases in the matrix, the strength of the interface, distribution of flaws in the reinforcement, and the distribution of the reinforcement within the composite. Consequently, predicting the strength of the composites from that of its constituent phases is generally difficult.

Production

A variety of techniques are available for the production of continuous or discontinuous MMCs. These may be broadly classified as diffusion processes, deposition processes, and liquid processes.

Fabrication

Composite processing methods combine the reinforcement with the matrix. This is accomplished while the matrix is either solid or liquid.

Typical liquid-state processes include the dispersion processes, which are casting techniques. A second set of processes involve liquid-metal impregnation; these include squeeze casting, where a preform or a bed of dispersoids is impregnated by molten alloy under hydraulic pressure. A third set comprises spray processes. In one of these, a molten metal stream is fragmented by means of a high-speed cold inert-gas jet passing through a spray gun, and dispersoid powders are simultaneously injected. A stream of molten droplets and dispersoid powders is directed toward a collector substrate where droplets recombine and solidify to form a high-density deposit.

Depending on the process, the desired microstructure, and the desired part, MMCs can be produced to net or near-net shape; or alternatively, they can be produced as billet or ingot material for secondary shaping and processing.

Applications

The combined attributes of MMCs, together with the costs of fabrication, vary widely with the nature of the material, the processing methods, and the quality of the product. In engineering, the type of composite used and its application vary significantly, as do the attributes that drive the choice of MMCs in design. For example, high specific modulus, low cost, and high weldability of extruded aluminum oxide particle-reinforced aluminum are the properties desirable for bicycle frames. High wear resistance, low weight, low cost, improved high-temperature properties, and the possibility for incorporation in a larger part of unreinforced aluminum are the considerations for design of diesel engine pistons.

Metallic Bond

The principal bond between metal atoms, which arises from the increased spatial extension of valence-electron wave functions when an aggregate of metal atoms is brought close together. An example is the bond formed between base metals and filler metals in all welding processes. See also *covalent bond* and *ionic bond*. See also *interatomic bonding*.

Metallic Fiber

A manufactured fiber composed of metal, plastic-coated metal, metal-coated plastic, or a core completely covered by metal.

Metallic Glass

A noncrystalline metal or alloy, commonly produced by drastic supercooling of a molten alloy, by molecular deposition, which involves growth from the vapor phase (e.g., thermal evaporation and sputtering) or from a liquid phase (e.g., electroless deposition and electrodeposition), or by external section techniques (e.g., ion implantation and ion beam mixing). Glassy alloys can be grouped into two major categories. The first group includes the transition metal–metal binary alloy systems, such as Cu–Zr, Ni–Ti, W–Si, and Ni–Nb. The second-class consists of transition metal–metalloid alloys. These alloys are usually iron-, nickel-, or cobalt-base systems, may contain film formers (such as chromium and titanium), and normally contain approximately 20 at.% P, B, Si, and/or C as the metalloid component. Also called amorphous alloy or metal. See also *amorphous solid*.

These are alloys with an amorphous and/or glassy structure. A glass is a solid material obtained from a liquid, which does not

M

crystallize during cooling. It is, therefore, an amorphous solid, which means that the atoms are packed in a more or less random fashion similar to that in the liquid state. The word *glass* is generally associated with the familiar transparent silicate glasses containing mostly silica and other oxides of aluminum, magnesium, sodium, and so on. These classes are not metallic; they are electrical insulators and do not exhibit ferromagnetism. One obvious answer to obtaining a glass having metallic properties is to start from a metal containing metallic elements instead of oxides.

Electrical and Superconductivity Properties

The electrical resistivity of metallic glasses is high, for example, $100 \mu\Omega \text{ cm}$ and higher, which is in the same range as the familiar nichrome alloys widely used as resistance elements in electric circuits. Another interesting characteristic of the electrical resistivity of metallic glasses is that it does not vary much with temperature. The temperature coefficient is of the order of 10^{-4} K^{-1} and can even be zero or negative, in which case the resistivity decreases with increasing temperature. Because of their insensitivity to temperature variations, metallic glasses are suitable for applications in electronic circuits for which the property is an essential requirement.

Superconducting metallic glasses are much more stable, and some of them do not crystallize at temperatures as high as 500°C . Some superconducting metallic glasses contain only two metals, such as $\text{Zr}_{75}\text{Rh}_{25}$, and some are more complex alloys in which there is approximately 20% of metalloid elements, mostly boron, silicon, or phosphorus.

One of the main reasons for continuing research on new superconducting glasses is their projected usefulness in high-field electromagnets, which will be required to contain the high-temperature plasma in fusion reactors. The present requirement for these magnets is a field of at least 100,000 G, which is not attainable with conventional copper-wound electromagnets. Observations and results have shown that the electrical resistivity of metallic glasses is not affected by radiation.

Magnetic Properties

The ferromagnetic properties of metallic glasses have received a great deal of attention, probably because of the possibility that these materials can be used as transformer cores. One class of ferromagnetic metallic glasses is based on transition metals with zirconia or hafnium, for example, $(\text{Co,Ni,Fe})_{90}\text{Zr}_{10}$.

Because metallic glasses do not have crystalline anisotropy, the core maker is able to anneal in a desired domain pattern. For example, metallic glasses can provide extremely high magnetic efficiency in motors because their anisotropy can be built in during a final annealing to develop a low-reluctance path in the exact configuration required by the motor. The use of metallic glasses in motors can reduce core loss by as much as 90% as compared with conventional crystalline magnets. Alternately, for transducer applications, one can just as well anneal in a domain structure that is transverse to the ribbon length by applying a transverse magnetic field during the annealing cycle. This will maximize the rotation of domains and hence the magnetostrain during any subsequent longitudinal excitation.

Mechanical and Other Properties

Although a metallic glass under tension will fracture with very small permanent deformation, scanning electron micrography reveals that a large local shear deformation occurs before rupture.

Metallic glasses thus are intrinsically ductile. The interest in the mechanical properties of metallic glasses is motivated by their high rupture strength and toughness. The fracture strength of metallic glasses approaches the theoretical strength that is about 1/50 of Young's modulus.

Future and Applications

Considering the unusual physical and chemical properties of metallic glasses, there is no doubt that they will play an important role as an engineering material in the future. The melt-spinning process of producing metallic glasses should also result in substantial savings in labor and energy when compared with the present technology because it can produce a thin sheet of material by direct casting from the liquid state.

Possible applications of metallic glasses have already been demonstrated on audio and video magnetic tape recording heads, sensitive and quick-response magnetic sensors or transducers, security systems, motors, and power transformer cores. The combination of excellent strength, resistance to corrosion and wear, and magnetic properties may lead to interesting applications, for example, the use of such glasses as inductors in magnetic separation equipment.

Besides the straightforward applications, there remain many less obvious potential applications of metallic glasses: the freedom from constraints imposed by the equilibrium phase diagram may well allow metallurgists to devise chemically interesting glassy alloys that could not be made otherwise in single-phase form. Glasses based on palladium-phosphorus alloys show a considerably higher catalytic activity for oxidation of methanol, and they are more stable than the fine-grained platinum electrodes. Another potential application of metallic glasses is their use when intentionally crystallized. Since glasses are highly supercooled liquids, crystallization can be affected via copious nucleation, which results in the formation of a fine-grained crystalline product that is microstructurally very homogeneous. An example is the use of a glass sheet of the alloy $\text{Ni}_{69}\text{Cr}_6\text{Fe}_3\text{B}_{14}\text{Si}_8$ as a brazing filler metal; the glass sheet can be stamped to shape and inserted between the parts to be joined, yielding excellent control of the joint properties after fusion of the products.

Another development is an application of powder-metallurgy methods to the fabrication of amorphous alloys. In the process of "atomizing" liquid alloys into a very fine powder, the rate of cooling may be high enough to produce an amorphous powder.

By using explosive loading, it is indeed possible to subject the powder to very high pressure, and probably some rather high temperature, for a very short enough time to avoid recrystallization, and to achieve near-theoretical densities. Massive ingots of metallic glasses, susceptible of being forged and rolled into various shapes, may become available within the not-too-distant future. Finally, since metallic glasses may be regarded as liquids whose structure has been frozen, they constitute ideal materials for low-temperature transport and critical behavior studies, and they are most suited for the study of electrons in noncrystalline metals.

Metallic Materials

About three quarters of the elements available can be classified as metals, and about half of these are of at least some industrial or commercial importance. Although the word *metal*, by strict definition, is limited to the pure metal elements, common usage gives it wider scope to include metal alloys. Although pure metallic elements have a broad range of properties, they are quite limited in commercial use. Metal alloys, which are combinations of two or more elements,

are far more versatile and for this reason are the form in which most metals are used by industry.

Metallic materials are crystalline solids. Individual crystals are composed of unit cells repeated in a regular pattern to form a three-dimensional crystal lattice structure. A piece of metal is an aggregate of many thousands of interlocking crystals (grains) immersed in a cloud of negative-valence electrons detached from the atoms of the crystals. These loose electrons serve to hold the crystal structures together because of their electrostatic attraction to the positively charged metal atoms (ions). The bonding forces, which are large because of the close-packed nature of metallic crystal structures, account for the generally good mechanical properties of metals. Also, the electron cloud makes most metals good conductors of heat and electricity.

Metals are often identified as to the method used to produce the forms in which they are used. When a metal has been formed or shaped in the solid, plastic state, it is referred to as a wrought metal. Metal shapes that have been produced by pouring liquid metal into a mold are referred to as cast metals.

There are two families of metallic materials—ferrous and nonferrous. The basic ingredient of all ferrous metals is the element iron. These metals range from cast irons and carbon steels, with over 90% iron, to specialty iron alloys, containing a variety of other elements that add up to nearly half the total composition.

Except for commercially pure iron, all ferrous materials, both irons and steels, are considered to be primarily iron–carbon alloy systems. Although the carbon content is small (less than 1% in steel and not more than 4% in cast irons) and often less than other alloying elements, it nevertheless is the predominant factor in the development and control of most mechanical properties.

By definition, metallic materials that do not have iron as their major ingredient are considered to be nonferrous metals. There are roughly a dozen nonferrous metals in relatively wide industrial use. At the top of the list is aluminum, which next to steel is the most widely used structural metal today. It and magnesium, titanium, and beryllium are often characterized as light metals because their density is considerably below that of steel.

Copper alloys are the second nonferrous material in terms of consumption. There are two major groups of copper alloys: brass, which is basically a binary alloy system of copper and zinc, and bronze, which was originally a copper–tin alloy system. Today, the bronzes include other copper–alloy systems.

Zinc, tin, and lead, with melting points below 427°C, are often classified as low-melting alloys. Zinc, whose major structural use is in die castings, ranks third to aluminum and copper in total consumption.

Lead and tin are rather limited to applications where their low melting points and other special properties are required. Other low-melting alloys are bismuth, antimony, cadmium, and indium.

Another broad group of nonferrous alloys is referred to as refractory metals. Such metals as tungsten, molybdenum, and chromium, with melting points above 1649°C, are used in products that must resist unusually high temperatures. Although nickel and cobalt have melting points below 1649°C, they serve as the base metal or as alloying elements of many heat-resistant alloys.

Finally, the precious metals, or noble metals, have a common characteristic of high cost. In addition, they generally have high corrosion resistance, many useful physical properties, and generally high density.

Metallic Soap

This is a term used to designate compounds of the fatty acids of vegetable and animal oils with metals other than sodium or potassium.

They are not definite chemical compounds like the alkali soaps, but may contain complex mixtures of free fatty acid, combined fatty acid, and free metallic oxides or hydroxides. The name distinguishes the water-insoluble soaps from the soluble soaps made with potash or soda. Metallic soaps are made by heating a fatty acid in the presence of a metallic oxide or carbonate, and are used in lacquers, leather and textiles, paints, inks, ceramics, and grease. They have the properties of being driers, thickening agents, and flattening agents. They are characterized by inability to gel in solvents and oils and by their catalytic action in speeding the oxidation of vegetable oils.

When made with fatty acids having high iodine values, the metallic soaps are liquid, such as the oleates and linoleates, but the resinates and tungates are unstable powders. The stearates are fine, very stable powders. They are found as barium, strontium, chromium, manganese, cerium, nickel, lead, and lithium stearates. The fatty acid determines the physical properties, but the metal determines the chemical properties. Aluminum stearate is the most widely used metallic soap for colloid products. Aluminum soaps are used in polishing compounds, in printing inks and paints, for water proofing textiles, and for thickening lubricating oils. The resinates, linoleates, and naphthenates are used as driers; the lead, cobalt, and manganese are the most common.

Metallic Wear

Typically, wear due to rubbing or sliding contact between metallic materials that exhibits the characteristics of severe wear, for example, significant plastic deformation, material transfer, and indications that cold welding of asperities possibly has taken place as part of the wear process. See also *adhesive wear* and *severe wear*.

Metallic Whisker

A fiber composed of a single crystal of metal. See also *whisker*.

Metallization

A deposited or plated thin metallic film used for its protective or electrical properties.

Metallizing

A process for applying a metal coating to the surface of a component that may be metal or other material. The term usually implies application by hot spraying or similar mechanical process rather than by a plating or diffusion processes. However, terms such as aluminizing or chromizing usually refer to diffusion processes.

Metallizing is the application of a metallic coating to a ceramic to permit subsequent brazing to a mating part. Various techniques are employed, but the basic steps follow the common practice of ceramic decorating except that materials must be carefully chosen.

Metallizing Systems

Metals

Reactivity being desirable, most metal powders are purchased as—325 mesh to ensure a high surface-to-volume ratio.

Copper

May be mixed, as flake, with coarse glass particles that melt and seal to the ceramic preserving the integrity of the flake. This continuous

M

electrical path through the glass seal is useful in the manufacture of spark plugs. Copper, as the oxide, will bond to a ceramic under precise firing conditions and, when mixed with silver, may be used as a metallizing preparation.

Gold

Frequently combined with reactive glass for uses in the air-fired paste and solder category.

Iron

Reactive material originally combined with tungsten. Very common additive for sintered powder process.

Manganese

Reactive material combined with molybdenum and is a very common additive.

Molybdenum

Most used as basic metal for sintered powder metallizing. Oxidation potential allows control of oxidation state in controlled atmosphere furnace. Coefficient of expansion of the metal and its reaction products are favorable.

Palladium

Similar to platinum and sometimes added to platinum–frit mixtures for air firing.

Platinum

Used with reactive glasses in air-fired metallizing.

Silver

Basic metal for many air-fired pastes. Mixed as granular or flake material with a reactive glass; for example, borosilicate.

Tin

Basis for direct chemical bonding to numerous ceramics and high-temperature metals.

Titanium

Basis of the active metals process. May be used as powder or foil prior to braze alloying. Titanium-bearing brazes will wet and flow over ceramic; in vacuum, almost as well as solder over copper. Frequently applied as the hydride, which disassociates at <800°C, providing nascent hydrogen, which tends to scour the surface to be wetted. May be added to sintered powder compositions to promote reaction.

Tungsten

Similar in metallizing properties to molybdenum.

Zirconium

Performs similarly to titanium, but with less activity. Has lower coefficient of expansion.

Miscellaneous Reactive Powders

Many companies have evolved proprietary sintered powder metallizing systems that may be very complicated. Some of the likely additives to these compositions are aluminum, barium, boron, cadmium, magnesium, rare earths, and silicon. Most of these would be added as an oxide.

Glass Compositions

Most metallizing suppliers purchase glass-bearing metallizing compositions from commercial vendors. The glass compositions are regarded as proprietary and are not generally known.

Binders

Binders are fugitive materials that are required to increase viscosity and density of the vehicles developed for suspending metal powders during application of the ceramic. They must leave no deleterious residue following the firing operation and must hold the metal *in situ* until the particles become somewhat adherent. Typical binders are represented by acrylic polymers, commercial binders, nitrocellulose, and pyroxyline resins.

Solvents

Solvents are required to dissolve the binder material and usually have a high vapor pressure, so they are effectively lost before firing of the metallizing begins. These materials, with the binders, constitute the vehicle. The best vehicles allow a smooth application with controlled thickness and dry to a dense abrasion-resistant layer prior to firing. Solvents are selected typically from the following families: acetates, alcohols, commercial solvents, ethers, and ketones.

Application Methods

Pastes, when used, are prepared by selecting the metal powders and blending with additives in a ball mill. Acetone is frequently used as the carrier during the milling operation. Attention is given to the desired degree of particle size reduction. The milled material is removed, dried, pulverized, and combined with the chosen binder and solvent. This preparation may be milled further to assure complete blending. The paste is then ready to be applied to the ceramic.

Many methods of application are in use. They vary depending on size of the order, configuration of the part, the precision required, and operating economy.

Brushing

A paintable slurry is prepared and applied by brush to the desired area of the ceramic. Useful for small lots or unusual configurations.

Decalcomania

Commercial sources offer patterns prepared for transfer to ceramic.

Dipping

Applicable where complete coverage is permissible or where subsequent methods of recovering a pattern are feasible.

Evaporation

Vacuum evaporation of metals offers a readily controllable metal thickness for thin film and other applications not requiring high strength.

Printing

Banding or printing equipment may be successfully used with certain pastes. Limitations result from ink thickness requirements.

Screening

A slurry is forced through a fine-mesh screen by a squeegee. This technique yields excellent patterns on cylindrical or flat surfaces.

Solution Metallizing

A liquid solution of the desired metal is supplied to the ceramic, subsequently dissociated, and then reduced to provide a metallic coating.

Spraying

Paint-spray techniques are adapted to metallizing. Masking is usually required on the part. High-volume production may be maintained.

Tapes

Metallizing compositions manufactured as a tape of controlled thickness are being offered commercially. The tape may be applied to the ceramic, adhered by solvent action, and fired.

Vapor Deposition

Reduction of chemical vapors, for example, nickel carbonyl, produces a uniform metallic layer on the ceramic. Deposition can be conventional or electrostatic firing.

Air Furnaces

Useful for glass-fritted pastes containing noble metal powders. Firing temperatures vary up to 1000°C.

Controlled Atmosphere Furnaces

Hydrogen or cracked ammonia atmospheres, with dew point and temperature controls, are typically used to react sintered-powder metallized coatings with ceramic. These furnaces operate at 1300°C–1700°C.

Vacuum Furnaces

Vacuum of 10^{-4} torr, or less, is required for metallizing and sealing by the active metals method. Vacuum evaporators operating in the 10^{-3} – 10^{-10} torr range are at present in use, experimentally, for studies of ultrapure metals deposited for two-dimensional circuitry requirements.

Others

While not yet of full commercial significance, work in plasma-jet technology and electron beam machining has significant potential.

Electroplating

Following firing, the active metal assembly hardware may be electroplated for ease of installation by user. Air-fired silver may be electroplated to improve solderability. Sintered-powder metallized ceramics must ordinarily be electroplated to allow wetting by solders or brazes. Many methods of electroplating are in use. Barrel plating is more economical than rack plating and is the preferred method. The thickness, purity, and type of electroplated metal have a significant effect on the effective strength of sintered-powder metallizing.

Etching

A chemical process used in conjunction with a masking system to create fine lines.

Metallograph

An optical instrument designed for visual observation and photomicrography of prepared surfaces of opaque materials at

magnifications of 25× to approximately 2000×. The instrument consists of a high-intensity illuminating source, a microscope, and a camera bellows. On some instruments, provisions are made for examination of specimen surfaces using polarized light, phase contrast, oblique illumination, dark-field illumination, and bright-field illumination.

Metallography

The practice of examining metals by microscopic techniques to establish their structure, reveal defects, and provide information on damage mechanisms or other matters of interest. The term macroscopic examination is often used for preliminary examination at low magnifications, say up to about 30×. This term is sometimes used to imply that the item being examined is in the as-received state, that is, it has not been polished or etched. Microscopic examination usually implies the examination, and a light microscope, of mounted and prepared specimens cut from a component. Typical practice involves cutting a piece of metal, say 10 mm² × 5 mm thick (1/2 × 1/4 in.), from the component under investigation. This is then encased, with the face of interest exposed, in a plastic resin to facilitate handling and to protect the edges that are often of particular interest. The face of interest is then ground flat prior to polishing, either mechanically or electrolytically. Mechanical polishing involves careful abrasion on a series of progressively finer grinding papers and polishing pads to provide a flat, mirror finish. Microscopic examination in this state provides some information on microstructure and damage mechanisms. However, some detail may be obscured by the surface deformation and smearing, termed the Beilby layer, produced by mechanical polishing. Such detail is revealed by etching whereby the specimen is exposed to acid or other reagents that remove the surface film or otherwise react selectively with features of interest. In some cases, the specimen may be electrolytically etched. This is essentially similar to the alternative polishing technique. Electrolytic polishing that involves making the specimen the anode of an electrolytic cell; see *electrochemistry*. With careful selection of reagents and control of the voltage and current, a flat, high-quality surface can be achieved. If necessary, the specimen may finally be etched. A conventional light microscope is a useful magnification of up to about 1000×. Examination at higher magnification normally requires the use of an electron microscope that uses an electron beam instead of light to examine the specimen. The system for producing the electron beam and projecting the image onto a screen is essentially a cathode ray tube similar to a television set. In the case of a transmission electron microscope (TEM), the metal samples to be examined are very thin and the electron beam travels through the specimen for projection on the screen or photographic film. In the case of a scanning electron microscope (SEM), the beam scans across, and is reflected from, the specimen surface prior to projection on the screen. Apart from the higher magnification, which is often not utilized, the SEM offers the major advantage that the electron beam has a very large depth of focus, so it can deal with a rough, irregular surface lying at an angle to the beam. The light microscope has only a shallow depth of focus, so it is effectively confined to flat surfaces aligned normal to the beam. This characteristic makes the SEM a valuable tool for examining fracture surfaces. The disadvantage of electron microscopy is that the specimen has to be small enough to be inserted into the instruments' vacuum chamber. With suitable ancillary equipment, the SEM can undertake analysis either of large areas to give a bulk composition or of small features such as inclusions or precipitates.

M

Metalloid

A material having some but not all of the characteristics of a metal, also termed a semi-metal.

Metallurgical Bond

Adherence of a coating to the base material characterized by diffusion, alloying, or intermolecular or intergranular attractions at the interface between the coating and the base material.

Metallurgical Burn

Modification of the microstructure near the contact surface due to frictional temperature rise.

Metallurgical Coke

A coke, usually low in sulfur, having a very high compressive strength at elevated temperatures; used in metallurgical furnaces not only as fuel, but also to support the weight of the charge.

Metallurgy

The science and technology of metals and alloys. Process metallurgy is concerned with the extraction of metals from their ores and with refining of metals; physical metallurgy, with the physical and mechanical properties of metals as affected by composition, processing, and environmental conditions; and mechanical metallurgy, with the response of metals to applied forces.

Metallock

Similar terms including some proprietary names. See *metal stitching*.

Metalworking

See *forming*.

Metastable

(1) Of a material not truly stable with respect to some transition, conversion, or reaction but stabilized kinetically either by rapid cooling or by some molecular characteristics as, for example, by the extremely high viscosity of polymers. (2) Possessing a state of pseudo-equilibrium that has a free energy higher than that of the true equilibrium state. (3) A nonequilibrium state in which a metal appears to be stable because it does not transform spontaneously (even over centuries). Essentially similar to unstable.

Metastable Beta

A β -phase composition in titanium alloys that can be partially or completely transformed to martensite, α , or eutectoid decomposition products with thermal or strain-energy activation during subsequent processing or service exposure.

Meter

(1) Metre. (2) A general term for a measuring instrument.

Methane

Also known as marsh gas, in coal mines as firedamp, and chemically as methyl hydride, methane is a colorless, odorless gas, CH_4 , employed for carbonizing steel, in the manufacture of formaldehyde, and as a starting point for many chemical compounds. The molecule has no free electrons and is the only stable carbon hydride, although it reacts easily on the no. 1 and 2 electrons of the carbon to form the hexagonal molecule called the benzene ring. It may thus be considered as the simplest of the vast group of hydrocarbons to rise from petroleum, coal, and natural gas. Methane occurs naturally from the decomposition plant and animal life and is also one of the chief constituents of illuminating gas. It is made synthetically by the direct union of carbon or carbon monoxide with hydrogen. It is also produced by the action of water on aluminum carbide.

Methane is also the chief constituent of natural gas from oil fields. Natural gas contains usually at least 75% methane. A new source of methane is a result of environmental cleanups. Methane is generated as a by-product during the biodegradation of polluted industrial waters and waste treatment plants. It is also obtained by tapping the gases produced as biomass matter degrades in municipal landfills.

Since 1990, to reduce air pollution, U.S. automakers have built cars, vans, and trucks fueled with natural gas for urban-area fleets. *Re-formed gas*, used for copper refining, contains 86% methane and is free of hydrogen sulfide and the higher homologs of methane. *Synthetic gas*, or oil gas, made from crude oil, can be had with an energy value equivalent to that of natural gas. *Sour gas* is natural gas with more than 1 g of hydrogen sulfide/100 ft³. This hydrogen sulfide is removed to eliminate the odor before it is piped. The propane, butane, and heavier hydrocarbons may also be removed for the production of chemicals.

Methyl Methacrylate

A colorless, volatile liquid derived from acetone, cyanohydrin, methanol, and dilute sulfuric acid and used in the production of *acrylic resins*.

Metre

The SI unit of length.

Metric System

The system of single standardized units for all properties, dimensions, etc., with all multiples or divisions to base 10. Now replaced by the SI system.

Metrology

The science and practice of measurement.

Meyer Index

A measure of the work hardening characteristics of a material determined by performing a series of hardness tests over a range of loads using a ball indenter. The index is then derived from a graph of the load against indentation diameter.

 M_f Temperature

For any alloy system, the temperature at which martensite formation on cooling is essentially finished. See also *transformation temperature* for the definition applicable to ferrous alloys.

M-Glass

A high beryllia (BeO_2) content glass designed especially for high modulus of elasticity.

MHO

An electrical unit of conductivity that is the conductivity of a body with the resistance of one ohm.

MIC

Mineral insulated cable.

Mica

Mica has been known as an electrical material of excellent insulating and fabricating properties for many years. Almost everyone has seen or used mica in one form or another, yet it is surprising how little even the average technically trained person knows about its composition, origin, and properties.

It is, of course, a naturally occurring mineral having a wide range of possible chemical compositions and properties. All true mica, however, belongs to one mineral class of silicates having a sheet type of structure, and found in certain areas of the world growing from pegmatite deposits in "book" form. In recent years, the increasing demands for high-quality sheet mica have led to the development and commercial production of synthetic mica as an electric furnace product.

Synthetic mica has recently been put into commercial production and is available in various powdered forms and organically bonded paper sheets; and a three-dimensional, hot-pressed, machinable synthetic mica ceramic; and in sheet form of limited area. Synthetic mica has unusually high thermal stability.

Of considerable interest to the refractories field is vermiculite, a form of mica that, on rapid heating, expands 16 times accordion-fashion to form a light and inert material suitable for use as a grog in refractories or as an aggregate for the production of lightweight casting refractory concretes.

Types

Mica comprises a group of hydrous aluminum silicate minerals with platy morphology in perfect basal (micaceous) cleavage. This group of silicate minerals has monoclinic crystals that break off easily into thin, tough scales, varying from colorless to black. Muscovite is the common variety of mica and is called potash mica or potash silicate. It has superior dielectric properties and is valued for radio capacitors.

Properties

The most singular outstanding property of mica is its physical structure. As a sheet mineral, it can be split into strong, flexible films with good high-temperature resistance and electrical insulating properties.

Uses

Commercial mica is of two main types: sheet, and scrap or flake. Sheet muscovite is used as a dielectric in capacitors in vacuum tubes and electronic equipment. Lower-quality muscovite is used as an insulator in home electrical products such as hot plates, toasters, and irons. Scrap and flake mica is ground for use in coatings on roofing

materials and waterproof fabrics, and in paint, wallpaper, joint cement, plastics, cosmetics, well-drilling products, and a variety of agricultural products.

For many years, glass-bonded mica has been used in every type of electrical and electronic system where the insulation requirements are preferably low-dissipation factor at high frequencies, a high-insulation resistance and dielectric-breakdown strength, along with extreme dimensional stability. Glass-bonded micas are made in both machinable grades and precision-moldable grades. Basically, the material consists of natural mica flake bonded with a low-loss electrical glass.

The availability of synthetic mica resulted in the development of so-called ceramoplastics, consisting of high-temperature electrical glass filled with synthetic mica. Ceramoplastics provide an increase in the electrical characteristics over those of natural mica, and, in addition, are more easily molded and have greater thermal stability.

Glass-bonded mica and ceramoplastics have found use in many advanced components such as telemetering commutation plates, molded printed circuitry, high-reliability relay spacers and bobbins, coil forms, transducer housing-miniature-switch cases, and innumerable other component applications.

Mica Powder

Mica is very small flakes used as a filler in plastics, in paints, in roofing and asphalt shingles, and for making glass-bonded mica. When produced by grinding the small scrap pieces from mica workings, it is known as **ground mica**.

Mixed with aluminum powder, mica produces a finished paint superior to aluminum alone. It has some activating properties and is a substitute for zinc oxide in rubber. It is also used as a filler in plastics and replaces graphite as a foundry core and mold wash. **Water-ground mica** is ground to a fineness of 90% through a 325-mesh screen. It is for paint and rubber use. **Micronized mica** is a powder of a fineness of 400–1000 mesh, used as a filler. **Mica flake**, used in the manufacture of shingles and roofing, is washed from pegmatite deposits, but the mica flake used for molding into mica ceramic electric insulators is ground phlogopite scrap, or from various compositions of synthetic mica.

Micelle

A submicroscopic unit of structure built up from ions or polymeric molecules.

Micro

In relation to reinforced plastics and composites, the properties of the constituents only, that is, matrix, reinforcements, and interface, and their effects on the properties of the composite.

Micro Alloyed Steel

Steels with alloying additions in small, but carefully selected and controlled, quantities. Under closely controlled manufacturing conditions, these steels are capable of giving a very fine grain size with high strength and with good ductility. Typical additions include aluminum, vanadium, titanium, and niobium of up to about 0.1% each. Some of these steels are also able to retain the high strength following welding, unlike more conventional steels that suffer softening of the zone adjacent to the weld. Also termed *High Strength Low Alloy Steel (HSLA)*.

M

Micro Analyzer

An analytical instrument essentially similar to, and often part of, an electron microscope. It is capable of focusing on and analyzing very small features on rolled or prepared specimens. Also see *metallography*.

Micro Cracking

Cracks formed in composites when thermal stresses locally exceed the strength of the matrix. Since most microcracks do not penetrate the reinforcing fibers, microcracks in a cross-plyed laminate or in a laminate made from cloth prepreg are usually limited to the thickness of a single ply.

Micro Inch

One millionth of an inch symbol μin .

Micro Metre

One millionth of a metre, a micron, symbol μm .

Microanalysis

(1) The analysis of samples smaller than 1 mg. (2) Various techniques for analyzing small quantities of material. A microprobe analyzer and similar terms including microanalyzer is an instrument associated with an electron microscope for analyzing small areas of surface.

Microbands

Long, straight bands of highly concentrated *slip* lying on the *slip planes* of individual grains in metals. They are usually 0.1–0.2 μm thick, traverse an entire grain, and correspond to the *slip bands* seen on a polished surface.

Microbial Attack/Corrosion

Corrosion caused, or assisted, by the presence of microbes, that is, bacteria, etc., in the surrounding environment. Microbes do not directly attack the metal, but their presence may modify the environment to make it more aggressive. See *biological corrosion*.

Microcap Shrinkage/Porosity, etc.

Phenomena observable only under a microscope or occurring on a very small scale.

Microcrack/Microfissure

A small crack not visible to the naked eye examination nor to the simplest form of nondistractive crack detection techniques.

Microdynamometer

An instrument for measuring mechanical force and observing the change in microscopic appearance of a small specimen.

Microelectromechanical Systems

A new discipline in miniaturization has emerged and is referred to as microelectromechanical systems (**MEMS**).

Three regions of “smallness” can now be identified. The “micro” region spans the dimensional range from micrometers to millimeters and is the most traditional. Here, MEMS/MST systems are dominant and contain such elements as micropressure sensors, accelerometers, microactuators, biochips, microswitches, and traditional MEMS and optical MEMS (*MOEMS*) components.

Another region that is beginning to attract considerable interest is the “nano” regime. It spans the nominal range from 100 nm down to 0.5 nm, a region in which the properties of many materials transition from those of macroscopic systems to become dominated by the discrete electronic states of molecular and atomic domains.

The nano regime has rich potential for offering useful new materials characteristics including enhanced strength and hardness, reduced resistivity, superplasticity, self-assembly, enhanced catalytic intensity, and increased magnetic and dielectric performance, to name a few.

A very short list of potential applications for nanostructured devices include field-emitter tips, carbon-fullerene nanotubular structures with electronic and superconducting potential, nanophase components for high-strength composite materials, more effective giant magnetoresistive structures for high-capacity magnetic data storage applications, a variety of proximal probe methods for high-density data reading, plus many more in the fields of chemistry, biology, and medicine.

Still a third regime of smallness, the mesoscale region, is beginning to achieve recognition. With dimensions in the submillimeter to centimeter range, mesoscale structures encompass complex composite systems of microcomponents. Examples, including some now being developed, including a mesoscale heat exchanger and a mesoscale vacuum pump. Both of these consist of arrays of individual microcomponents acting in concert. In addition, many microinstrumentation packages such as those now under development for medical applications and space exploration may qualify for re-categorization as mesosystems.

Microelectronics

The area of electronic technology associated with or applied to the realization of electronic systems from extremely small electronic parts or elements.

Microengineering

Microengineering is the design and production of small, three-dimensional objects, usually for manufacturing high volumes at low cost. Such designs have a wide range of applications, including automobiles, medicine, aircraft, printing, security, and insurance. The techniques employed come from a wide range of disciplines, including biochemical, chemical, electrical, electronic, fluidic, mechanical, and optical engineering. Present designs occupy a volume of about 1 mm^3 (40 mils³) and are made in tolerances of a few micrometers (about 50 μin).

The applications of the described sensors cover air-bag sensors, which detects crashes and sets off an air-bag.

Microengineering is also used to provide automatic braking systems and intelligent suspension for smoother rides, and to optimize the flame profile in an engine to reduce fuel consumption.

The process uses synchrotron radiation to produce sharp cuts in thick-film photoresists, which may then be plated with plastics, metals, or other materials. The use of nickel produces strong metal parts in substantial quantities. In one design, these are assembled to produce a very small motor, which is suitable for use in microsurgery, watches, and camcorders.

Fiber clamps, gyroscopes, fuses, water-quality monitoring, patient monitoring, eye surgery microsurgery, printing, aviation, and food production are just some of the applications and processing methods being utilized and considered under microengineering. In the United States, MEMS covers the electronic and mechanical parts of microengineering. In Japan, the term *micromachines* is used to cover a small specific subset that includes sensors and robots. In Europe, the terms *microsystems* and *microsystems technology* cover systems and the technologies used to make them, but usually only the use of semiconductor-like processing; they also exclude the many small devices that operate independently.

The term *nanoengineering* is usually used to describe even smaller devices, nominally 1000 times smaller, which are usually much more expensive and are not normally mass produced. The term *mechatronics* covers the use of mechanical and electronic engineering irrespective of size.

Microetching

Development of microstructure for microscopic examination. The usual magnification exceeds 25 $\times$ (50 $\times$ in Europe).

Microfissure

A crack of microscopic proportions.

Micrograph

A graphic reproduction of the surface of a specimen and a magnification greater than 25 $\times$. If produced by photographic means, it is called a photomicrograph (not a microphotograph).

Microgrinding

This technology offers benefits for optical materials manufacturers where lapping and finishing alternatives can provide reduced cycle time and increased quality in the manufacture of optical components.

In deterministic microgrinding, the infeed rate, rather than the nominal pressure, is kept constant. This manufacturing operation uses rigid, computer-controlled machining centers and high-speed tool spindles. The system eliminates the specialized tooling, special skills, and long cycle times required with conventional equipment—cycle time reductions of 50% have been routinely achieved.

The equipment is capable of surfacing, edging, centering, and beveling in one setup sequence. The grinding geometry uses a bound abrasive cup wheel that is rotated at high speed and tilted at a very precise angle. Specular surfaces, resulting after less than 5 min of deterministic microgrinding, have a typical rms microroughness of less than 20 nm.

Because the equipment uses sequential cuts with coarse, medium, and fine grinding wheels, it takes only about 10 min to grind each surface. The fine wheel was run at 15,000 rpm and is fed into the lens at 6 $\mu\text{m}/\text{min}$. In less than 3 min, a total of 15 μm of material was removed, which is equal to the depth of the subsurface cracks produced by the medium tool. When used at slow infeed rates and for appropriate removal tasks, the 2–4 μm tools can cut hundreds of parts without needing to be redressed.

Finishing can be defined as the production of the surface to within 0.25 μm (peak to valley) of the specified shape and under 20 $\text{\AA}$ rms finish. Conventional finishing processes are time-consuming and labor-intensive and can require much rework.

A new finishing technology has been developed that addresses these problems.

Called magnetorheological (MR) finishing, the method is based on an MR fluid, a suspension of noncolloidal magnetic particles (usually carbonyl iron in water with smaller concentrations of stabilizers) and finishing abrasives (cerium oxide). This viscous liquid becomes a solid when a DC magnetic field is applied to it; stiffness is directly proportional to field strength. The MR fluid can be thought of as a compliant replacement for the conventional rigid lap in the loose abrasive grinding and finishing process. A magnetic field applied to the fluid creates a temporary finishing surface, which can be controlled in real time by varying the strength and direction of the field.

Surface smoothing, removal of subsurface damage, and figure correction are accomplished by rotating the part on a spindle at a constant speed while sweeping the lens about its radius of curvature through the stiffened finishing zone.

With the standard MR fluid, MRF reduces the surface microroughness of fused silica and other optical materials to less than 10 $\text{\AA}$ rms. The time required to do this varies from 5 to 60 min, depending on the material and its initial roughness. If the initial rms surface microroughness is less than 30 nm, smoothing occurs in 5–10 min.

Microhardness

The hardness of a material as determined by forcing an indenter such as a Vickers or Knoop indenter into the surface of a material under very light load; usually, the indentations are so small that they must be measured with a microscope. Capable of determining hardness is of different microconstituents within a structure, or of measuring steep hardness gradients such as those encountered in *case hardening*. See also *microhardness test*.

Microhardness Number

A commonly used term for the more technically correct term *microindentation hardness number*.

Microhardness Test

A microindentation hardness test using a calibrated machine to force a diamond indenter of specific geometry, under a test load of 1–1000 gf, into the surface of the test material and to measure the diagonal or diagonals optically. See also *Knoop hardness test* and *Vickers hardness test*.

Microindentation

(1) In hardness testing, the small residual impression left in a solid surface when an indenter, typically a pyramidal diamond stylus, is withdrawn after penetrating the surface. Typically, the dimensions of the microindentations are measured to determine microindentation hardness number, but newer methods measure the displacement of the indenter during the indentation process to use in the hardness calculation. The precise size required to qualify as a microindentation has not been clearly defined; however, typical measurements of the diagonals of such impressions range from approximately 10 to 200 μm , depending on normal force and material. (2) The process of indenting a solid surface, using a hard stylus of prescribed geometry and under a slowly applied normal force, usually for the purpose of determining its microindentation hardness number. See also *Knoop hardness number*, *microindentation hardness number*, and *Vickers hardness number*.

M

Microindentation Hardness Number

A numerical quantity, usually stated in units of pressure (kg/mm^2), that expresses the resistance to penetration of a solid surface by a hard indenter a prescribed geometry and under a specified, slowly applied normal force. The preface “micro” indicates that the indentations produced are typically between 10.0 and 200.0 μm across. See also *Knoop hardness number*, *nanohardness test*, and *Vickers hardness number*.

Microinfiltrated Macrolaminated Composites

Ceramics offer attractive properties, including good high-temperature strength and resistance to wear and oxidation. However, the major limitation to their use in structural applications is their inherent low fracture toughness, that is, the tendency to break (fracture) and produce low values. Ceramics have low fracture toughness, whereas steels and superalloys have better fracture toughness. Methods currently being used to improve the toughness of ceramics involve the incorporation of reinforcing whiskers and fibers; inclusion of a phase that undergoes transformation within the stress field associated with a crack; and cermet technology (cermet/metal composites), in which the tough metallic component absorbs energy. Improved toughness is attributed to various mechanisms, including crack branching, transformation-induced residual stresses, crack bridging, and energy absorption by plastic flow.

Another possible approach to improving the toughness of ceramics is via laminated construction. Sophisticated coating techniques have been used to produce laminated microstructures of ceramics and metals, but the cost of producing a bulk-laminated composite of useful size is prohibitive. Fabrication of microinfiltrated macrolaminated composites offers an economically feasible approach to produce a variety of cermet/metallic and ceramic/metallic bulk-laminated composites. The basic architecture of a microinfiltrated macrolaminated composite is a double-layer structure. One layer consists of a soft, ductile material having a low modulus of elasticity, low strength, and high toughness; the second layer consists of a hard, brittle material having a high modulus of elasticity and low toughness. This double layer is repeated as many times as necessary to form the bulk composite; in addition, the brittle material is infiltrated with the ductile constituent.

Advantages

The architecture of the microinfiltrated macrolaminated composite offers a compromise to the conventional composite microstructure by providing repeated alternating layers of bulk tough metallic and brittle cermet and ceramic materials. Any crack introduced into the brittle constituent will, upon entering the metallic interlayer, be subjected to a potential crack, stopping higher toughness.

Composition and Fabrication

Fabrication of microinfiltrated macrolaminated composite materials offers a processing route to economical manufacture of large, bulk laminated composites in which an interpenetrating microstructure is achievable. Use of both ceramic and metal powders in the process opens the door to a potentially wide range of material combinations. The same fundamental processing steps can be used to produce a wide variety of microinfiltrated macrolaminated composites, including ceramic/metal, metal/intermetallic, and ceramic/intermetallic systems.

Various combinations of composite properties, including hardness, strength, ductility, and fracture toughness, are possible by varying the laminate layer thicknesses. Microinfiltrated macrolaminated

composites, when used in bulk form, are expected to have properties far superior to those of the individual monolithic constituents of the composite.

Alternative processing routes for microinfiltrated macrolaminated composites are available if the composite constituents have some solubility for one another, such as in the tungsten carbide–cobalt/cobalt (WC–Co/Co) and tungsten–nickel–iron heavy alloy/nickel (W–Ni–Fe/Ni) systems. In general, to obtain a large composite of this type, the best approach is to use the tape-casting process (well known in the ceramic industry) to produce large thin tapes (sheets) of the material.

Consolidation (compaction) helps the material achieve its full density by removing gas voids, porosity, and so forth. An attractive alternative for producing sheets consists of rolling the powder material followed by sintering to the required percent of theoretical density, retaining a certain level of interconnected porosity.

The fabrication steps used to make a W–Ni–Fe/Ni microinfiltrated macrolaminated composite illustrate the process. Tungsten powder is tape cast, and the sheets are sintered to 60%–70% of theoretical density, which produces totally interconnected porosity. Small amounts of nickel can be used together with tungsten to promote activated sintering and to produce a porous tungsten sheet that can be handled safely. Sheet thickness ranges from 1 to 10 mm.

An 80:20 ratio of nickel and iron powders also is tape-cast and sintered to full density. Sheets of porous tungsten and fully dense nickel–iron alloy material are laid up in alternate layers and heated to about 1475°C, which is about 40°C above the melting point of the nickel–iron alloy. The molten Ni–Fe alloy infiltrates the porous tungsten sheets and takes into solution a fraction of the tungsten. A thin layer of the liquid phase can be retained between the tungsten sheets after the infiltration process is complete. This retention is possible if the tungsten sheet contains porosity levels that are lower than the volume of liquid formed by melting the nickel–iron sheets.

Applications

The design of microinfiltrated macrolaminated composites could prove advantageous in applications involving impact or ballistic penetration. The metallic interlayer would function to hold together damaged portions of the brittle constituent. Thus, the development of ceramic armor having multihit capability becomes possible. Current metal/ceramic composite armor is layered on an extremely macroscopic scale. An approach involving microinfiltrated macrolaminated composites permits optimization of layer frequency and thickness to resist specific threats, as in antipersonal weapons or armored vehicles.

In addition, high-temperature composites, consisting of a ceramic and intermetallic compound, such as aluminum oxide/nickel aluminide (Ni_3Al) plus boron, could be fabricated in the form of microinfiltrated macrolaminated composites to yield combinations with new properties. Ultrahigh-temperature composites incorporating temperature ceramics and ductile niobium is another potential application to obtain various combinations of high wear resistance and toughness. The hard ceramic outer layer would provide a wear-resistant surface, with toughness provided by the ductile material. A similar concept could lead to a new generation of cutting tools, in which the outer most cutting layer could be made of ultrahard materials suitably layered with a soft, ductile constituent for toughness.

Other potential applications are in heat- and oxidation-resistant, low-density structural components and aerospace parts having low density, high strength and modulus, and good fracture toughness.

Finally, the reinforcement of concrete with carbon fibers is a recently developed technique for the construction of structures

such as buildings, bridges, and tunnels. Advantages of carbon-fiber reinforcement include outstanding electromagnetic shielding, high resistance to corrosive environments, light weight, and high mechanical property strength. Two methods are used to achieve the reinforcement: mixing carbon fibers, either chopped or mat, directly into cement (carbon fiber-reinforced concrete); and using carbon fiber/plastic composites in rod or tape form for strengthening the concrete.

Micromachining

Magnetron plasma etching has been found to be a promising technique for micromachining of single-crystal silicon carbide to fabricate microscopic structures comprising integrated mechanical, electronic, and optical devices. Silicon carbide offers several advantages over silicon for the development of future devices. In comparison with silicon, silicon carbide is harder and stiffer, is less chemically reactive, and has greater thermal conductivity; moreover, silicon carbide-based electronic devices can operate at temperatures higher than silicon-based electronic devices can withstand. Etching techniques for micromachining of silicon are well known, but the lesser chemical reactivity of silicon carbide makes it necessary to devise alternative etching techniques.

In the present magnetron-plasma-etching technique as in the ECR etching technique, a magnetic field is used to increase the density of the plasma. Unlike in ECR etching, the main body of the plasma is confined in proximity to the sample. Such confinement results in a high concentration of reactive chemical species together with a high flux of bombarding ions at the sample, making it possible to achieve rapid etching.

Magnetron plasma etching of SiC was demonstrated in preliminary experiments in a vacuum chamber using a magnetron sputter gun as a cathode. The duration of each edge was 7 min. At a radiofrequency power of 250 W, a maximum edge depth of 4.5 μm was achieved with a gas mixture of $0.6\text{CHF}_3 + 0.4\text{O}_2$ at a total pressure of about 2.7 Pa. This depth corresponds to an etch rate of about 640 nm/min, which is a relatively high rate, significantly higher than that which has been achieved using an ECR plasma. The etched surface was found to have a rms surface roughness of only 20 Å. The reaction of aluminum and fluorine yields a nonvolatile product, which makes aluminum suitable for use as a mask material to provide selective etching in fluorine-based plasmas. At the radiofrequency power of 250 W, aluminum films were etched at a high rate. At a radiofrequency power of 50 W, silicon carbide was etched at a rate of 170 nm/min, while aluminum was etched at 1/12 that rate.

Micromesh

A sieve with precisely square openings in the range of 10–120 μm produced by electroforming.

Micromesh Sizing

The process of sizing micromesh particles using an air or a liquid suspension process.

Micrometer

(1) Any instrument for measuring earlier dimensions at high precision. (2) A dimension of 0.001 mm, written with the abbreviation μm . Also referred to as micron (not recommended).

Micron

One millionth of a meter, symbol μm . This is not an SI-approved name.

Micropore

The pores in a sintered product that can only be detected under a microscope.

Microporosity

Extremely fine porosity in castings.

Microprobe Analyzer

Same as *micro analyzer*.

Micropulverizer

A machine that disintegrates powder agglomerates by strong impacts from small hammers fastened to a solid disk that rotates at very high velocity.

Microradiography

The technique of passing x-rays through a thin section of a material in contact with a fine-grained photographic film and then viewing the radiograph at 50 $\times$ to 100 $\times$ to observe the distribution of constituents and/or defects.

Microscope

Unless otherwise indicated, this term usually refers to the light microscope. This is a multilens instrument for examining a material at a high magnification. Biological microscopes project a beam of light through the specimen under examination. This light is then focused through a system of magnifying lenses to form an image at the observer's eye. Basically two lenses are involved, the objective close to the specimen which produces the initial image that is then magnified by the ocular or eyepiece close to the observer. In practice, age of the lenses is of compound form, that is, form from multiple individual lenses, some spaced apart, some bonded together. The total magnification is approximately the multiple of the ocular and objective. A metallurgical microscope is similar except that the light beam is injected into the body of the microscope between the objective and eyepiece. It is initially reflected by a clear glass plate reflector onto the specimen and then reflected back along its original path through the objective, straight through the clear reflector and ocular into the eye. In any microscope, the objective lens is responsible for developing the initial image so that its numerical aperture, that is, its efficiency in gathering light is critical and the wavelength of light is such that details finer than about 0.2 μm cannot be resolved by the objective lens. This corresponds to an objective lens magnification of about 100 $\times$ diameters, so useful magnification of the microscope ranges up to about 1000 $\times$ diameters. At the highest magnifications, an immersion oil may be interposed in the very small gap between the specimen and the objective lens to approve the resolution. See also *electron microscope* and *metallography*.

Microscopic

Invisible at magnifications above 25 $\times$.

M

Microscopic Stress

Residual stress in a material within a distance comparable to the grain size. See also *macroscopic stress*.

Microscopical Examination

See *metallography* and *microscope*.

Microscopy

The science of the interpretive use and applications of microscopes and examining materials under a microscope.

Microsection

A sample of metal cut from a component, etc., for metallographic examination.

Microsegregation

Segregation within a grain, crystal, or small particle. See also *coring*.

Microshrinkage

A casting imperfection, not detectable microscopically, consisting of inner dendritic voids. Microshrinkage results from contraction during solidification where the opportunity to supply filler material is inadequate to compensate for shrinkage. Alloys with wide ranges in solidification temperature are particularly susceptible.

Microshrinkage Cavity

A fine void found microscopically in the low melting metal phase of infiltrated powder metallurgy compacts due to contraction during solidification.

Microslip

(1) Small relative tangential displacement in a contacting area at an interface, when the remainder of the interface in the contacting area is not relatively displaced tangentially. Microslip can occur in both rolling and stationary contacts. (2) The term microslip is sometimes used to denote the microslip velocity. This usage is not recommended. See also *macroslip* and *slip*.

Microspheres

Spherical particles used in plastics and other materials as fillers and reinforcing agents. They are also used to encapsulate various materials. Those used as fillers or reinforcements are made of glass or ceramics or resins. There are two different kinds of glass microspheres—solid and hollow. Solid spheres, made of soda-line glass, range in size from 157 to 197,000 μin . (4 to 5,000 μm) in diameter and have a specific gravity of about 2.5. Hollow glass microspheres have densities ranging from 5 to 50 lb/ft^3 (80 to 801 kg/m^3) and diameters from 790 to 7900 μin . [20 to 200 μm]. The spheres in plastics improve tensile, flexural, and compressive strengths and lower elongation in water absorption. Hollow, glass, **microballoon microspheres**, of Emerson and Cuming can be as small as 200 μin . (5 μm). **Plastic microspheres** are used mostly in the production of

syntactic foams. *Polyvinylidene chloride microspheres* are excellent resin extenders and are used in sandwich construction of boat hulls. *Epoxy microspheres* are used as low-density bulk fillers for plastics and ceramics and were developed for use in submerged deep-water floats. *Phenolic microspheres* filled with nitrogen are used for production of polyester foams and syntactic epoxy foams. Polystyrene microspheres are also used to produce syntactic foams.

In the pharmaceutical industry, microspheres are used to encapsulate active ingredients. Multilayered *liposome microspheres* are typically made of fatty acids or lipid materials. Liposome formation takes advantage of the amphipathic nature of fat molecules, which allows fats to form liposomes spontaneously in turbulent water. For injectable drugs, nontoxic and biocompatible phospholipids, such as lecithin, cephalin, and phosphatidyl inositol, are used for less demanding applications, liposomes can be made from fatty acids, alkyl derivatives, and amines. Microsponges, made from cross-linked polymers, are used as time-release delivery systems of process ingredients.

Microstrain

The strain over a gauge length comparable to interatomic distances. These are the strains being averaged by the *macrostrain* measurement. Microstrain is not measurable by existing techniques. The variance of the microstrip distribution can, however, be measured by x-ray diffraction.

Microstress

Same as *microscopic stress*.

Microstress/Microstrain

Stresses and strains that either are of very low magnitude or act over very short distances relative to the context.

Microstructure

(1) The structure of an object, organism, or material as revealed by a microscope at magnifications greater than 25 $\times$. (2) The arrangement and features of grains, phases, inclusions, and other features within a metal. It is normally examined by light or electron microscope.

Microtome

Equipment for slicing a very thin film or sheet of material from some larger item, usually for some form of examination or test.

Microwave Heating

A microwave-heating technique provides for batch processing of multiple, identically sized and shaped samples of the same material. The technique involves (1) excitation of asymmetrical electromagnetic mode or modes in a asymmetrical microwave cavity and (2) positioning the samples symmetrically in the cavity so that all samples are exposed to the same electromagnetic field conditions and thus the same heating conditions. Typically, the electromagnetic modes and the pattern for mounting the samples are chosen to maximize the heating effect and make it as nearly spatially uniform as possible.

The same principle can be applied to microwave heating of multiple spherical or disk-shaped samples.

Microwave Radiation

Electromagnetic radiation in the wavelength range of 0.3 mm to 1 m (3×10^6 to 10^{10} Å). See also *electromagnetic radiation*.

Middle-Infrared Radiation

Infrared radiation in the wavelength range of 3–30 μm (3×10^4 to 3×10^5 Å). See also *infrared radiation* and *electromagnetic radiation*.

Middling

A product intermediate between concentrate and tailing and containing enough of a valuable mineral to make retreatment profitable.

MIG Welding

See preferred term *gas metal arc welding*.

Migration

Movement of entities (such as electrons, ions, atoms, molecules, vacancies, and grain boundaries) from one place to another under the influence of a driving force (such as an electrical potential or a concentration gradient).

Mil

(1) An English measure of thickness or diameter equal to 0.0254 mm (0.001 in.). A common designation of wire size, coating thickness, or corrosion loss. (2) Either 1000th of an inch or 1 mm. Both uses are informal, and the potential for confusion is obvious.

Mild Steel

Carbon steel with a maximum of about 0.25% C and containing 0.4%–0.7% Mn, 0.1%–0.5% Si, and some residuals of sulfur, phosphorus, and/or other elements.

Mild Wear

A form of wear characterized by the removal of material in very small fragments. Mild wear is an imprecise term, frequently used in research and contrasted with severe wear. In fact, the phenomena studied usually involve the transition from mild to severe wear and the factors that influence this transition. Mild wear may be appreciably greater than can be tolerated in practice. With metallic sliders, mild wear debris usually consists of oxide particles. See also *normal wear* and *severe wear*.

Military Transformation

A transformation from one phase to another in which the atoms at the advancing interface act in a relatively restricted manner and can be constrained to certain crystallographic orientations or confined by some of the original phase grain boundaries.

Mill

(1) A factory in which metals are hot worked, cold worked, or melted and cast into standard shapes suitable for secondary fabrication into commercial products. (2) A production line, usually of four or more

stands, for hot or cold rolling metal into standard shapes such as bar, rod, plate, sheet, or strip. (3) A single machine for hot rolling, cold rolling, or extruding metal; examples include *blooming mill*, *cluster mill*, *four-high mill*, and *Sendzimer mill*. (4) A shop term for a milling cutter. (5) A machine or group of machines for grinding or crushing ores and other minerals. (6) A machine for grinding or mixing material, for example, a ball mill and a paint mill. (7) Grinding or mixing a material, for example, milling a powder metallurgy material.

Mill Edge

The normal edge produced in hot rolling of sheet metal. This edge is customarily removed when hot-rolled sheets are further processed into cold-rolled sheets.

Mill Finish

(1) A nonstandard (and typically nonuniform) surface finish on *mill products* that are delivered without being subjected to a special surface treatment (other than a corrosion preventative treatment) after the final working or a heat-treating step. (2) Material in the state in which it left the last major manufacturing operation, such as rolling drawing or extrusion. As examples, mill finished hot rolled plate will have wide tolerances on dimensions and carry a heavy oxide coating, termed mill scale, while mill finished cold-rolled material will have a smooth surface or even a deliberately textured or embossed surface but will not have been polished and perhaps not thoroughly cleaned. See also *milled finish*.

Mill Product

Any commercial product of a *mill*.

Mill Scale

The heavy oxide layer that forms during the hot fabrication or heat treatment of metals. See *magnetite* and *mill finish*.

Milled Fiber

Continuous glass strands hammer milled into very short glass fibers. Useful as inexpensive filler or anticrazing reinforcing fillers for adhesives and engineering plastics.

Milled Finish

Material that has been machined on a milling machine and hence will have a bright surface and, probably, precise dimensions. In some cases, the repetitive pattern of circular swirl marks characteristic of some milling operations is seen as aesthetically pleasing. Note, however, that a similar effect is sometimes achieved by abrading a sheet surface with a flat end polishing bob. See also *mill finish*.

Miller Bravais Indices

See *Miller Indices*.

Miller Indices

A system for identifying planes and directions in any crystal system by means of sets of integers. The indices of a plane are related to the intercepts of that plane with the axes of a unit cell; the indices

M

of a direction, to the multiples of lattice parameter that represent the coordinates of a point on a line parallel to the direction and passing through the arbitrary chosen origin of a unit cell.

This is a system for identifying planes and orientations in a crystal lattice. It is best considered in three steps. In the simple case of a cubic system, three axes *X*, *Y*, and *Z* radiate from an origin at the corner of the cube unit cell. At step 1, the plane of interest is specified by measuring the distance, from the origin, at which it intercepts the three axes. Such distances are measured in terms of the unit cell size.

Step 2 is to take the reciprocal of the three intercept units from step 1, giving 1.0/0 and 1.1/1, which are the *Miller Indices*. Step 3 only necessary for planes less simple than those just discussed, requires these reciprocals to be factored to give the smallest possible whole numbers, that is, *X*, 1/2, 1, would be factored to 0, 1, 2, and 2, 4, 6, would be factored to 1, 2, 3. Miller Indices are conventionally enclosed in parentheses, the use of simple brackets (111) indicating all planes lying parallel to the reference plane, while in irregular brackets {111} indicate all planes having similar atomic structures but lying in all directions.

Directions, derived by identifying the intercepts of the line on the axes, are indicated by square brackets [111]. If any of the intercepts at step 1 had been negative, it would be identified in the Index by a bar above it. The more complex case of hexagonal structures is dealt with by Miller–Bravais Indices by reference to four axes, the *W*, *X*, and *Y* axes at 120° on the basal plane and the *Z* axis normal to the basal plane.

Miller Number

A measure of slurry abrasivity as related to the instantaneous mass-loss rate of a standard metal wear block at a specific time on the cumulative abrasion–corrosion time curve. See also *slurry abrasion response number*.

Milling (Machining)

Using a rotary tool with one or more teeth that engage the workpiece and remove material as the workpiece moves past the rotating cutter.

1. *Face milling*: Milling a surface perpendicular to the axis of the cutter. Peripheral cutting edges remove the bulk of the material, while the face cutting edges provide the finish of the surface being generated.
2. *End milling*: Milling accomplished with a tool having cutting edges on its cylindrical surfaces as well as on its end. In peripheral end milling, the peripheral cutting edges on the cylindrical surface are used; while in slotting, both end and peripheral cutting edges remove metal.
3. *Side and slot milling*: Milling of the side or slot of a workpiece using a peripheral cutter.
4. *Slab milling*: Milling of a surface parallel to the axis of a helical, multiple-toothed cutter mounted on an arbor.
5. *Straddle milling*: Peripheral milling a workpiece on both sides at once using two cutters as required.

Milling (Powder Technology)

The mechanical comminution of a material, usually in a ball mill, to alter the size or shape of the individual particles, to coat one component of a mixture with another, or to create uniform distributions of components.

Milling Cutter

A rotary cutting tool provided with one or more cutting elements, called teeth, which intermittently engage the workpiece and remove material by relative movement of the workpiece and cutter.

Milling Fluid

An organic liquid, such as hexane, in which *ball milling* is carried out. The liquid serves to reduce the heat of friction and resulting surface oxidation of the particles during grinding, and to provide protection from other surface contamination.

Millstone

Any stone employed for grinding paint, cement, grain, or minerals. Millstones are made from sandstone, basalt, granite, or quartz conglomerate. *Burrstone* is a millstone made from chalcedony silica of cellular texture, usually yellowish. The stone is used as a building stone.

Pulpstones are blocks of sandstone cut into wheels and used for grinding, chiefly for the grinding of wood pulp in paper manufacture. The sandstones for pulpstones must be uniform in texture, have sharp grains, have medium hardness, and be composed of even quartz grains of which 85% will be retained on a 150-mesh screen, and 90% on a 200-mesh screen. The cement milling material may be siliceous, calcareous, or argillaceous, but must be firm enough to hold the stone together when working under pressure, and soft enough to wear faster than the quartz grains and prevent glazing. Large pulpstones for paper mills are now made of silicon carbide or aluminum oxide in fitted sections.

Mineral Dressing

(1) Preliminary actions to prepare an ore for the main process of extracting the metal. The term includes physical processes and, usually, initial chemical concentrating processes. (2) Physical and chemical concentrations of raw ore into a product from which a metal can be recovered at a profit.

Mineral Insulated Cable (MIC)

An electrical cable comprising an outer tubular copper sheath and one or more bare copper conductors, the gap between them being filled with compacted magnesium oxide powder as insulant.

Mineral Oil

A refined hydrocarbon oil without animal or vegetable additives.

Mineral Wool

A fibrous material employed as a heat insulator in walls or as a sound insulator. It was first obtained as a natural product from volcanic craters in Hawaii and was known as *Pele's hair*. It is made by mixing stone with molten slag from blast furnaces and blowing steam through it. Slags from copper and lead furnaces are also used. *Slag wool* is made from slag without the rock. A lead slag containing 30%–50% calcium and magnesium oxides makes a mineral wool that withstands temperatures up to 1500°F (816°C) when made into blocks or boards. Mineral wool usually consists of a mass of fine, pliant, vitreous fibers, which are incombustible and non

conductors of heat. *Rock wool* is made by blowing molten rock in the same manner and is more uniform than common mineral wool, with physical qualities depending, however, on the class of rock used. *Rock cork* is a name for a low-temperature insulating material made of rock wool molded in sheet form with a waterproof binder, used for walls in cold-storage rooms. *Mineral-wool board* is a moisture-resistant board for cold-storage insulation. *Mono-Block* is rock wool made into standard blocks and slabs by a felting process.

Granulated mineral wool is the fiber milled into pellets, and these pellets can be poured into a space for insulation, or they may be pressed into insulating blocks. *Rockwool quilt* consists of felted fibers stitched between layers of Kraft paper for wall insulation.

Selected minerals, to give various characteristics, may be used to make rock wools. Wollastonite is melted to produce a rock wool. It is also ground to a white vesicular powder of 30–350 mesh for use as a filler in molded plastics. The grains are minute fibers. *Ceramic fiber* differs from mineral wool in that it is made of special composition. *Aluminum silicate fiber* is made by melting alumina and silica and passing the molten material through a stream of high-pressure air that produces a fluffy mass of extremely fine fibers up to 3 in. (7.62 cm) long. The melting point of the fibers about 3000°F (1649°C), but the maximum usable temperature is about 2300°F (1260°C), as the fibers devitrify at higher temperatures. The fibers are used for thin insulating paper, panel board, filler for plastics, and chemical-resistant rope or are woven into fabrics. Aluminum silicate fabrics are used for filters, gaskets, belting, insulation, and protective clothing. Fiberfrax, of Carborundum Co., is an aluminum silicate fiber.

Miners Rule

A means for estimating fatigue life when a component is subjected to a series of different stresses. For each stress level, the number of cycles experienced is expressed as a fraction of the number of cycles to failure at that stress. Failure occurs when the sum of the fractions is unity.

Minimized Spangle

A hot dip galvanized coating of very small grain size, which makes the *spangle* less visible when the part is subsequently painted.

Minimum Bend Radius

The minimum radius over which a metal product can be bent to a given angle without fracture. See also the term *bend radius*.

Minimum Load ($P_{\min}$)

In fatigue, the least algebraic value of applied load in a cycle.

Minimum Stress ($S_{\min}$)

In fatigue, the stress having the lowest algebraic value in the cycle, tensile stress being considered positive and compressive stress negative.

Minimum Stress-Intensity Factor ($K_{\min}$)

In fatigue, the minimum value of the *stress-intensity factor* in a cycle. This value corresponds to the *minimum load* when the *load ratio* >0 and is taken to be zero when the load ratio is ≤ 0 .

Minor Segregation

See *segregation*.

Minus Sieve

The portion of a powder sample that passes through a standard sieve of a specified number. See also *plus sieve* and *sieve analysis*.

Mirror Illumination

A thin, half-round opaque mirror interposed in a microscope for directing an intense oblique beam of light to the object. The light incident on the object passes through one half of the aperture of the objective, and the light reflected from the object passes through the other half aperture of the objective.

Mirror Region

The comparatively smooth region that symmetrically surrounds a fracture origin in ceramics and glasses. The mirror region ends in a microscopically irregular manner at the beginning of the mist region. See also *mist hackle*.

Mischmetal

A natural mixture of rare earth elements (atomic numbers 57–71) in metallic form. It contains about 50% cerium, the remainder being principally 40% lanthanum and neodymium. Mischmetal is used as an alloying additive in ferrous alloys to scavenge sulfur, oxygen, and other impurities and in magnesium alloys to improve high-temperature strength. Alloys with iron or magnesium, it is pyrophoric, and used for lighter “flints.”

Miscibility

The ability of two or more liquids to mix forming a single homogeneous solution.

Miscibility Gap

A region of multiphase equilibrium. It is commonly applied to the specific case in which an otherwise continuous series of liquid or solid solutions is interrupted over a limited temperature range by a two-phase field terminating at a critical point. See also *binodal curve*.

Miscible

Of two phases, the ability of each to dissolve in the other. May occur in a limited range of ratios of the two, or in any ratio.

Mismatch

The misalignment or error in register of a pair of forging dies; also applied to the condition of the resulting forging. The acceptable amount of this displacement is governed by blueprint or specification tolerances. Within tolerances, mismatch is a condition; in excess of tolerance, it is a serious defect. Defective forgings can be salvaged by hot-reforging operations.

M

Misrun

Denotes an irregularity on a cast metal surface caused by incomplete filling of the mold due to low pouring temperatures, gas back pressure from inadequate venting of the mold, and inadequate gating and cold shuts.

Mist

An area of dull flat tensile fracture observed on some brittle fractures.

Mist Hackle

Markings on the surface of a crack in ceramics and glasses accelerating close to the effective terminal velocity, observable first as a mist on the surface and with increasing velocity revealing a fibrous texture elongated in the direction of cracking and coarsening up to the stage at which the crack bifurcates. Velocity bifurcation or velocity forking is the splitting of a single crack into two mature diverging cracks or at near the effective terminal velocity of about half the transverse speed of sound in the material. See also *bifurcation* and *mirror region*.

Mist Lubrication

Lubrication by an oil mist produced by injecting oil into a gas stream.

Mitchell Bearing

See *tilting-pad bearing*.

Mixed Dislocation

See *dislocation*.

Mixed Grain Size

See *duplex grain size*.

Mixed Lubrication

See *quasi-hydrodynamic lubrication*.

Mixed Potential

The potential of a specimen (or specimens in a *galvanic couple*) when two or more electrochemical reactions are occurring. Also called galvanic couple potential.

Mixing

In powder metallurgy, the thorough intermingling of powders of two or more different materials (not *blending*).

Mixing Chamber

The part of a torch or furnace burner in which gases are mixed.

MMA Welding

See *Manual Metal Arc Welding*.

Mobile Phase

In chromatography, the gas or liquid that flows through the chromatographic column. A sample compound in the mobile phase moves through the column and is separated from compounds residing in the stationary phase. See also *stationary phase*.

Mock

When used as prefix to gold, silver, etc., it indicates a wide range of alloys of base metals claimed to have a superficial resemblance to the metal implied.

Mock Leno Weave

An open fabric weave for composites that resembles a leno and is accomplished by a system of interlacings that draws a group of threads together and leaves a space between that group and the next. The warp threads do not actually cross each other as in a real leno and, therefore, no special attachments are required for the loom. This type of weave is generally used when a high thread count is required for strength, and the fabric must remain porous. See the term *leno weave*.

Mode

One of the three classes of crack (surface) displacements adjacent to the crack tip. These displacement modes are associated with stress-strain fields around the crack tip and are designated I, II, and III. See also *crack-tip plane strain*, *crack opening displacement*, and *fracture mechanics*.

Moderator

In a nuclear reactor context, a material having a low atomic weight and low capture cross section that slows down fast neutrons allowing them to be captured by the fuel causing fission.

Modification

Treatment of molten hypoeutectic (8%–13% Si) or hypereutectic (13%–19% Si) alumina–silicon alloys to improve mechanical properties of the solid alloy by refinement of the size and distribution of the silicon phase. Involves additions of small percentages of sodium, about 0.02%–0.05%, strontium, or calcium (hypoeutectic alloys) or of phosphorus (hypereutectic alloys), as well as sodium chloride or fluoride, is added to the molten metal to refine the normally coarse eutectic structure that develops on solidification.

Modified Acrylic

A thermoplastic polymer that has been altered to eliminate mixing, curing ovens, and odor and that cures rapidly at room temperature.

Modifier

Any chemically inert ingredient added to an adhesive formulation to change its properties. Compare with *filler*, *plasticizer*, and *extender*.

Modulus of Elasticity (*E*)

(1) The measure of rigidity or stiffness of a material; the ratio of stress, below the proportional limit, to the corresponding strain. In the tensile stress of 13.8 MPa (2.0 ksi) results in an elongation of 1.0%, the modulus of elasticity is 13.8 MPa (2.0 ksi) divided by 0.01, or 1380 MPa (200 ksi). (2) In terms of the *stress–strain curve*, the modulus of elasticity is the slope of the stress–strain curve in the range of linear proportionality of stress to strain. Also known as *Young's modulus*. For materials that do not conform to Hooke's law throughout the elastic range, the slope of either the tangent to the stress–strain curve at the origin or at low stress, the secant drawn from the origin to any specified point on the stress–strain curve, or the chord connecting any two specific points on the stress–strain curve is usually taken to be the modulus of elasticity. In these cases, the modulus is referred to as the *tangent modulus*, *secant modulus*, or *chord modulus*, respectively.

Modulus of Resilience

The amount of energy stored in a material when loaded to its elastic limit. It is determined by measuring the area under the *stress–strain curve* up to the *elastic limit*. See also *elastic energy*, *resilience*, and *strain energy*. See also *Limit of Proportionality*.

Modulus of Rigidity

See *shear modulus*.

Modulus of Rupture

(1) A measure of the strength of a material determined in a three-point bend test. The test is usually applied to brittle materials as it avoids the problem associated with gripping the specimen that arises in the tensile test. (2) Nominal stress at fracture in a bend test or torsion tests. In bending, modulus of rupture is the bending moment at fracture divided by the section modulus. In torsion, modulus of rupture is the torque at fracture divided by the polar section modulus. See also *modulus of rupture in bending* and *modulus of rupture in torsion*.

Modulus of Rupture in Bending (*S_b*)

The value of maximum tensile or compressive stress (whichever causes failure) in the extreme fiber of a beam loaded to failure in bending computed from the flexure equation:

$$S_b = \frac{M_c}{I}$$

where

M is the maximum bending moment, computed from the maximum load and the original moment arm

c is the initial distance from the neutral axis to the extreme fiber where failure occurs

I is the initial moment of inertia of the cross section about the neutral axis

See also *modulus of rupture*.

Modulus of Rupture in Torsion (*S_s*)

The value of maximum shear stress in the extreme fiber of a member of circular cross section loaded to failure in torsion computed from the equation:

$$S_s = \frac{T_r}{J}$$

where

T is the maximum twisting moment

r is the original outer radius

J is the polar moment of inertia of the original cross section

See also *modulus of rupture*.

Modulus of Strain Hardening

See preferred term *rate of strain hardening*.

Modulus of Toughness

The amount of work per unit volume of a material required to carry that material to failure under static loading. See also *toughness*.

Mohs Hardness Number

A scale of hardness according to a scale proposed by Mohs, based on 10 minerals, each of which would scratch the one below it. These metals, in decreasing order of hardness, are as follows:

Diamond	10	Apatite	5
Corundum	9	Fluorite	4
Topaz	8	Calcite	3
Quartz	7	Gypsum	2
Feldspar	6	Talc	1

Moiety

A portion of a molecule, generally complex, having a characteristic chemical property.

Moiré Pattern

A pattern developed from interference or light blocking when gratings, screens, or regularly spaced patterns are superimposed on one another.

Moisture Absorption

The pickup of water vapor from air by a polymeric material, in reference to vapor withdrawn from the air only, as distinguished from water absorption, which is the gain in weight due to the absorption of water by immersion.

Moisture Content

The amount of moisture in a polymeric material determined under prescribed conditions and expressed as a percent of the mass of the moist specimen, that is, the mass of the dry substance plus the moisture.

M**Moisture Equilibrium**

The condition reached by a plastic sample when it no longer takes up moisture from, or gives up moisture to, the surrounding environment.

Moisture Regain

The moisture in a polymeric material determined under prescribed conditions and expressed as a percent of the weight of the moisture-free specimens. Moisture regain may result from either sorption or desorption, and it differs from moisture content only in the basis used for calculation.

Moisture Vapor Transmission (MVT)

A rate at which water vapor passes through a polymeric material at a specified temperature and relative humidity.

Molal Solution

Concentration of a solution expressed in moles of solute divided by 1000 g of solvent.

Molality

The number of gram-molecular weights of a compound dissolved in 1 L of solvent. See also *gram-molecular weight*. Compare with *molarity* and *normality*.

Molar Conductivity

The electrical conductivity of a solution containing the molecular weight in grams dissolved in 1 L of water.

Molar Heat

The molecular weight in grams $\times$ the specific heat in grams per $^{\circ}\text{C}$.

Molar Solution

Aqueous solution that contains 1 mole (gram-molecular weight) of solute in 1 L of the solution.

Molarity

The number of gram-molecular weights of a compound dissolved in 1 L of solution. See also *gram-molecular weight*. Compare with *molality* and *normality*.

Mold (Metals)

(1) The form, made of sand, metal, or refractory material, that contains the cavity into which molten metal is poured to produce a casting of desired shape. (2) A die.

Mold (Plastics)

The cavity into which, or matrix on which, the plastic composition is placed and from which it takes form. To shape plastic parts or finished articles by heat and pressure. The assembly of all the parts that function collectively in the molding process.

Mold Cavity (Metals)

The space in a mold that is filled with liquid metal to form the casting upon solidification. The channels through which liquid metal enters the mold cavity (sprue, runner, gates) and reservoirs for liquid metal (risers) are not considered part of the mold cavity proper.

Mold Coating (Metals)

(1) Coating to prevent surface defects on permanent mold castings and die castings. (2) Coating on sand molds to prevent metal penetration and to improve metal finish. Also called mold facing or mold dressing.

Mold Jacket (Metals)

Wood or metal form that is slipped over a sand mold for support during pouring of a casting.

Mold Release Agent (Plastics)

A lubricant, liquid, or powder (often silicon oils and waxes) used to prevent sticking of molded plastic articles in the cavity.

Mold Shift (Metals)

A casting defect that results when the parts of the mold do not match at the parting line.

Mold Shrinkage (Plastics)

(1) The immediate shrinkage that a molded plastic part undergoes when it is removed from a mold and cooled to room temperature. (2) The difference in dimensions, expressed in inches per inch, between a molding and the mold cavity in which it was molded (at normal-temperature measurement). (3) The incremental difference between the dimensions of the molding and the mold from which it was made, expressed as a percentage of the mold dimensions.

Mold Steel

This is a term that generally refers to the steels used for making molds for molding plastics. Mold steel should have a uniform texture that will machine readily with die-sinking tools. It must have no microscopic porosity and must be capable of polishing to a mirrorlike surface. When annealed, it should be soft enough to take the deep imprint of a bob, and when hardened, it must be able to withstand high pressure without sinking and have sufficient tensile strength to prevent breakage of thin mold sections. And, it should be dimensionally stable during heat treatment and corrosion-resistant to the plastics being formed.

The principal mold steels are the P-type mold steels, specifically P6, which contains 0.10% carbon, 3.50% nickel, and 1.50% chromium; P20 (0.35% carbon, 1.70% chromium, and 0.40% molybdenum); and P21 (0.20% carbon, 4.00% nickel, and 1.20% aluminum). P6 is a carburizing steel having moderate hardenability, P20 also has only moderate hardenability, but P21 is a deep-hardening steel. P20 and P21 are usually supplied hardened to R_c 30–36, in which condition they can be machined to complex shapes. P21, a precipitation-hardening steel, can be supplied moderately hard, then machined and post hardened by a moderate-temperature age.

Mold Surface (Plastics)

The side of a laminate that faced the mold (tool) during cure in an autoclave or hydroclave.

Mold Wash (Metals)

An aqueous or alcoholic emulsion or suspension of various materials used to coat the surface of a casting mold cavity.

Various fluids, for example, a suspension of graphite in water or paraffin, which is applied to the faces of a mold prior to casting to improve surface finish, reduce the damage to reusable molds, and assist stripping. Release agents are similar, but this term tends to be applied to more sophisticated products for smaller precision products.

Molded Edge (Plastics)

An edge on a plastic part that is not physically altered after molding for use in final form, particularly one that does not have fiber ends along its length.

Molded Net (Plastics)

Description of a molded plastic part that requires no additional processing to meet dimensional requirements.

Molding (Plastics)

The forming of a polymer or composite into a solid mass of prescribed shape and size by the application of pressure and heat for a given time. The finished part.

Molding Compound (Plastics)

Plastic material in varying stages of pellet form or granulation (powder), consisting of resin, filler, pigments, reinforcements, plasticizers, and other ingredients, ready for use in the molding operation. Also called molding powder.

Molding Cycle (Plastics)

The period of time required for the complete sequence of operations on a molding press to produce one set of plastic moldings. The operations necessary to produce a set of moldings without reference to the total time.

Molding Machine (Metals)

A machine for making sand molds by mechanically compacting sand around a pattern. See the term *jolt ramming* and *jolt-squeezer machine*.

Molding Press (Metals)

A press used to form powder metallurgy compacts.

Molding Pressure (Plastics)

The pressure applied to the ram of an injection machine, compression press, or transfer press to force the softened plastic to fill the mold cavities completely.

Molding Sands

Foundry sands containing over 5% natural clay, usually between 8% and 20%. See also *naturally bonded molding sand*.

Mole

One mole is the mass numerically equal (in grams) to the relative molecular mass of a substance. It is the amount of substance of a system that contains as many elementary units (6.02×10^{23}) as there are atoms of carbon in 0.012 kg of the nuclide ^{12}C ; the elementary unit must be specified and may be in an atom, molecule, ion, electronic, photon, or even a specified group of such units.

Mole Fraction

The number of atoms of one element, as a percentage of the total number of atoms in a material or phase.

Molecular Fluorescence Spectroscopy

An analytical technique that measures the fluorescence emission characteristic of a molecular, as opposed to an atomic species. The emission results from electronic transitions between molecular states and can be used to detect and/or measure trace amounts of molecular species.

Molecular Mass

The sum of the atomic mass of all atoms in a molecule. In *high polymers*, because the molecular masses of individual molecules vary widely, they must be expressed as averages. The average molecular mass of polymers may be expressed as number-average molecular mass or mass-average molecular map.

Molecular Materials

Matter of nanoscale dimensions often displays properties unlike those of isolated gas-phase molecules or the bulk liquids or solids that they make up. These unusual properties are often attributable to the unique bonding, structure, and morphology that small systems of finite dimensions adopt, whereas in other cases they result because the small sizes bring about new phenomenon arising from what is termed *quantum confinement*, the restriction of space available to electrons. Because of the special properties that these cluster systems (aggregates of atoms or molecules) display, they have become an active subject of basic investigation in recent years. Often, impetus for such research has arisen from the promise that new advanced materials might be produced by assembling nanoscale systems.

Investigations into the reactions of small hydrocarbons with transition metal ions, atoms, and clusters led to the discovery of an unexpected dehydrogenation reaction leading to the assembly of a new molecular cluster family termed metallocarbohedrenes (met-cars).

Met-Car Composition and Structure

The surprising finding that a heretofore unknown compound composed of transition metal and carbon atoms was very stable, and displayed unique bonding far different than that of the well-known cubic structure of bulk titanium carbide, prompted a search for other clusters with similar compositions.

The first successful alternative method involved the laser vaporization of well-mixed powders of selected metals and graphite, followed by the entrainment of the formed product species in pulses of helium gas. Met-cars were readily produced with appropriate conditions of laser power and metal-to-carbon ratio mixtures. Thereafter, it was found that met-cars could be produced from a mixture of

M

metal carbides along with carbon and metal powders by vaporizing them in a small crucible suspended in vacuum, without any need for a gas to transport the plasma or assist in its cooling.

An important advance toward exploring the potential use of these molecular clusters as new materials came from successful attempts to synthesize bulk quantities of met-cars. Synthesizing was first accomplished with an arc-discharge technique similar to ones that have been used to produce so-called buckyballs (fullerenes).

Future Status

Met-cars have been established as a new class of molecular cluster materials that are likely to have unusual properties and many potential applications. It has been observed that these molecular clusters readily ionize even at very low intensities of light of widely varying wavelengths, suggesting that they have a substantially delocalized electronic character and that they may display unique optical and perhaps electrical properties.

All the evidence points to their structure as one in which the metal and carbon atoms are bound in a well-defined lattice with one type of metal site. The formation of these interesting materials appears to be dominated by kinetic effects involving MC_2 building units. The clusters are found to grow by a unique mechanism leading to the development of a multicaged extended network structure.

Work is actively being pursued to isolate large amounts of bulk material and study the exact geometry and properties of met-cars using conventional chemical and physical techniques. Of particular interest is elucidating their optical, electronic, and reactive properties, through the use of molecular beams, lasers, and flow reactors.

Molecular Seal

A seal that is basically of the windback type, but that is used for sealing vapors or gases.

Molecular Spectrum

The spectrum of electromagnetic radiation emitted or absorbed by a collection of molecules as a function of frequency, wave number, or some related quantity.

Molecular Structure

The manner in which electrons and nuclei interact to form a molecule, as elucidated by quantum mechanics and the study of molecular spectra.

Molecular Weight

(1) The sum of the atomic weights of all the atoms in a molecule. Atomic weights (and therefore molecular weights) are relative weights arbitrarily referred to an assigned atomic weight of exactly 12.0000 for the most abundant isotope of carbon, ^{12}C . See also *atomic weight*. (2) The weight of the smallest quantity of a substance that has all the physical characteristics of the substance, referred to the weight of a molecule of hydrogen defined as 2 or a molecule of oxygen defined as 32 or a molecule of carbon defined as 12.

Molecule

(1) A molecule may be thought of either as a structure built of atoms bound together by chemical forces or as a structure in which two

or more positively charged nuclei are maintained in some definite geometrical configuration by attractive forces from the surrounding cloud of electrons. Besides chemically stable molecules, short-lived molecular fragments termed free radicals can be observed under special circumstances. See also *chemical bonding*, *free radical*, and *molecular structure*. (2) Two or more atoms bonded together by sharing electrons to form the smallest quantity of a substance that has all the physical characteristics of the substance. The two or more atoms may be the same element, for example, two atoms of hydrogen will normally join together to form a hydrogen molecule, H_2 . Alternatively, the atoms may be different, for example, two atoms of hydrogen will join with one atom of oxygen to form water, H_2O . See also *inter-atomic bonding*.

Molten Metal Flame Spraying

A thermal spraying process variation in which the metallic material to be sprayed is in the molten condition. See also *flame spraying*.

Molten Metal Penetration

Penetration, usually at grain boundaries, of molten metal into a solid metal, usually under stress, either applied or residual. Such penetration is usually a plane of weakness, and cracks may form immediately or later in service. There are many examples including lead, solder, copper, brass (which is sufficiently common to have its own term brazing penetration) in sync penetration into steel (it has been suggested that austenitic steel is particularly sensitive to zinc), and of the lower melting point materials into copper and brass. It is a particular form of liquid-metal attack.

Molten Weld Pool

The liquid state of a weld prior to solidification as weld metal.

Molybdenum and Alloys

Molybdenum (Mo) is a silvery-white metal, occurring chiefly in the mineral molybdenite but also obtained as a by-product from copper ores. The metal has a specific gravity of 10.2 and a melting point of 2610°C . It is ductile, softer than tungsten, and is readily worked or drawn into very fine wire. It cannot be hardened by heat treatment, but only by working.

Its major use is in alloy steels, for example, as tool steels ($\leq 10\%$ molybdenum), stainless steel, and armor plate. Up to 3% molybdenum is added to cast iron to increase strength. Up to 30% molybdenum may be added to iron-, cobalt-, and nickel-base alloys designed for severe heat- and corrosion-resistant applications. It may be used in filaments for light bulbs, and it has many applications in electronic circuitry.

Molybdenum forms mirrors and films on glass when it is produced by gas-phase reduction or decomposition of volatile molybdenum compounds in glass tubes. Also, because the molybdenum metal surface binds strongly to oxygen without weakening the metal structure, and because the metal has such a low coefficient of thermal expansion—virtually equal to hard glass—molybdenum metal is an extraordinarily good material for use in glass-metal seals. Molybdenum trioxide (MoO_3) dissolves in glass, allowing strong binding of molten glass with preoxidized metal surfaces. Annealing is very effective, with little or no difference in thermal expansion at the metal–glass interface. Molybdenum found early use in filaments for electric light bulbs and later in the construction of electronic devices (e.g., in vacuum tubes, contacts, electrodes, and transistors).

Protection from Oxidation

At temperatures over about 538°C, unprotected molybdenum oxidizes so rapidly in air or oxidizing atmospheres that its continued use under these conditions is impractical. Uncoated molybdenum is, however, used satisfactorily where very short lives are involved (as in some missile parts) or where the surrounding atmosphere is non-oxidizing (as in hydrogen and vacuum furnaces). Protective coatings seem to be the answer where oxidation is a problem. Various coatings differing in maximum time-temperature capabilities and in physical and mechanical characteristics are available. Selection of the proper coating for a specific application involves consideration of a number of factors, foremost among which is the service temperature. For temperatures up to 1204°C, nickel-base alloys applied as cladding or sprayed coatings, and chromium-nickel electroplates appear most generally suitable. For temperatures up to 1538°C, or short periods at higher temperatures, modified chromized coatings and sprayed aluminum-chromium-silicon are predominant. For longer periods at higher temperatures, the choice would probably rest between siliconizing and ceramic coatings. Component tests have been found most reliable for final selection of suitable coatings.

Applications

The applications of molybdenum are generally those based on its high melting point, high modulus of elasticity, high strength at elevated temperatures, high thermal conductivity, high resistance to corrosion, low specific heat, and low coefficient of expansion. Long-established uses are found in the electric and electronic industries for applications such as mandrels and supports in lamp fabrication, anodes and grids in electronic tubes, resistance elements and radiation shields in high-temperature furnaces, and electrical contacts and electrodes. In recent years, molybdenum has become increasingly important in the missile field for nozzles, nozzle inserts, leading edges of control surfaces, and support vanes. Uses in the metalworking industry include boring bars, grinding quills, resistance-welding electrodes, and thermocouples. The nuclear-energy industry has been active in developing molybdenum heat exchangers, piping, heat shields, and structural parts. The glass industry is a major user of large molybdenum parts, especially for melting electrodes and stirrers. The chemical and petrochemical industry is beginning to use molybdenum for corrosion resistance. The usefulness of molybdenum as a metallized coating, either to improve bonding between the base metal and a sprayed top coating, or alone for improved wear resistance, is no longer confined to maintenance but is extending to original equipment.

Alloys

Four main classes of commercial molybdenum-base alloys exist. One class relies on the formation of fine metal carbides that strengthen the material by dispersion hardening and extend the resistance of the microstructure to recrystallization above that of pure molybdenum.

The most common of the carbide-strengthened alloys is known as TZM, containing about 0.5% titanium, 0.08% zirconium, and 0.03% carbon. Other alloys in this class include TZC (1.2% titanium, 0.3% zirconium, 0.1% carbon), MHC (1.2% hafnium, 0.05% carbon), and ZHM (1.2% hafnium, 0.4% zirconium, 0.12% carbon). The high-temperature strength imparted by these alloys is their main reason for existence.

Both TZM and MHC have found application as metalworking tool materials. Their high-temperature strength and high thermal

conductivity make them quite resistant to the collapse and thermal cracking that are common failure mechanisms for tooling materials. A particularly demanding application is the isothermal forging process used to manufacture nickel-base superalloy gas-turbine engine components. In this process, the dies and workpiece are both heated to the hot working temperature, and the forging is performed in a vacuum by using large hydraulic presses.

A second class relies on solid-solution hardening to strengthen molybdenum. These two classes of materials are typically produced in both vacuum-arc-casting and powder metallurgy grades. In the solid-solution class, tungsten and rhenium are the two primary alloying additions. The most common compositions are 30% tungsten (Mo-30% W), 5% rhenium (Mo-5% Re), 41% rhenium (Mo-41% Re), and 47.5% rhenium (Mo-50% Re). With the exception of the Mo-30% W alloy, which is available as a vacuum-arc-cast product, these alloys are normally produced by powder metallurgy. The tungsten-containing alloys find application as components in systems handling molten zinc because of their resistance to this medium. They were developed as a lower-cost, lighter-weight alternative to pure tungsten and have served these applications well over the years. The 5% rhenium alloy is used primarily as thermocouple wire, whereas the 41% and 47.5% alloys are used in structural aerospace applications.

The third class uses combinations of carbide formers and solution partners to provide improved high-temperature strength. This class of alloys is normally produced by powder metallurgy techniques, but some of the alloys are also amenable to vacuum-arc-casting processing.

The beneficial effects of solid-solution hardening and dispersion hardening found in the carbide-strengthened alloys have been combined in the HWM-25 alloy (25% tungsten, 1% hafnium, 0.07% carbon). This alloy offers high-temperature strength greater than that of carbide-strengthened molybdenum, but it has not found wide commercial application because of the added cost of tungsten and the expense of processing the material.

The final class of alloys, known as dispersion-strengthened alloys, relies on second-phase particles (usually an oxide of a ceramic material) introduced or produced during powder processing to provide resistance to recrystallization and to stabilize the recrystallized grain structure, and enhancing high-temperature strength and improving low-temperature ductility. These latter materials by their very nature must be produced by powder metallurgy techniques.

The dispersion-strengthened alloys rely exclusively on powder metallurgy manufacturing techniques. This allows the production of fine stable dispersions of second phases that stabilize the wrought structure against recrystallization, resulting in a material having improved high-temperature creep strength as compared to pure molybdenum. Once recrystallization occurs, the dispersoids also stabilize the interlocked recrystallized grain structure. This latter effect produces significant improvements in the ductility of the recrystallized material.

The potassium- and silicon-doped alloys such as MH (150 ppm potassium, 300 ppm silicon) and KW (200 ppm potassium, 300 ppm silicon, 100 ppm aluminum) are the oldest of this category; they are analogous to the doped tungsten alloys in common use for tungsten lamp filaments. They were first developed to satisfy the requirement of the lighting industry for creep-resistant molybdenum components. They do not possess particularly high strength at low temperatures, but they are quite resistant to recrystallization and they possess excellent creep resistance due to their stable, interlocked recrystallized grain structure. They are used in applications requiring high-temperature creep resistance such as nuclear fuel sintering boats.

M

Composites

A family of copper–molybdenum–copper (CMC) laminates has been developed to serve the needs of the high-performance electronics industry. Laminating molybdenum with copper raises the coefficient of thermal expansion and improves the heat-transfer characteristics of the composite relative to pure molybdenum. This allows better matching between the composite that serves as a packaging or mounting material and the solid-state devices being employed.

Molybdenum Disilicide

The commercial product contains approximately 60% molybdenum, 31% silicon, 8% iron, with small amounts of carbon, sulfur, vanadium, phosphorus, and copper. Its principal use is for alloying iron and steel, but it has ceramic uses as well. Its outstanding resistance to oxidation in air at temperatures up to 1700°C makes it potentially useful for high-temperature applications.

The excellent resistance to oxidation at high temperatures combined with fairly good elevated temperature strength makes MoSi₂ promising for elevated temperature structural applications where impact resistance is not a major consideration. Possible uses are gas turbine nozzle blades and furnace heating elements. Also, a metal–ceramic combination of MoSi₂ and Al₂O₃ has been considered for use as kiln furniture, saggers, sand blast nozzles, hot-draw or hot-pressed dies, and induction brazing fixtures.

Molybdenum Steel

Next to carbon, molybdenum is the most effective hardening element for steel. It also has the property, like tungsten, of giving steel the quality of red hardness, requiring a smaller amount for the same effect. It is also used in hot-work steels, and to replace part of the tungsten in high-speed steels. It is added to heat-resistant irons and steels to make them resistant to deformation at high temperatures and to creep at moderate temperatures. It increases the corrosion resistance of stainless steels at high temperatures. Molybdenum in small amounts also increases the elastic limit of steel, reduces grain size, strengthens crystalline structure, and gives deep hardening. It goes into solid solution, but when other elements are present, it may form carbides and harden the steel, giving greater wear resistance. It also widens the heat-treating range of tool steels. As it decreases the temper brittleness of aluminum steels, small amounts are added to nitriding steels.

Plain carbon–molybdenum steels are easier to machine than other steels of equal hardness. Molybdenum structural steels usually have from 0.20% to 0.75% molybdenum. SAE (formally Society of Automotive Engineers) steels 4130 and 4140 contain about 1.0% chromium and 0.20% molybdenum and are high-strength forging steels for such uses as connecting rods. Hollow-head screws are made of SAE 4150 steel, and SAE steels 4615 and 4650 have no chromium but contain about 1.75% nickel and 0.25% molybdenum. SAE 4615 is used for molds and dies to be hobbled. It is easily worked and has a tensile strength of 1482 MPa. Finally, the old Damascus steel and Toledo steel were molybdenum steels; the molybdenum was in the original ore.

Moly–Manganese Process

A common method of joining oxide ceramics (most commonly of alumina) whereby a mixture of molybdenum and manganese powders (typically 10 at% Mn) is applied on the ceramic surface, and then sintered to bond to the ceramic. The sintering temperature is usually above 1400°C (2500°F) in a hydrogen atmosphere with a

controlled dewpoint. Subsequent nickel plating in conjunction with this Mo–Mn metallized layer facilitates the application and adherence of brazing filler metals that would not bond to the original ceramic substrate.

Moment

The turning action of a force acting about a point. It is the product of the force and the perpendicular distance from the line of action of the force to the point.

Mond Process

A process for extracting and purifying nickel. The main features consists of forming nickel carbonyl by reaction of finely divided reduced metal with carbon monoxide, then decomposing the nickel carbonyl to deposit purified nickel on small nickel pellets.

Monel

Alloys of nickel containing about 30% copper with small quantities of iron, manganese, and aluminum. Various alloys generally offer good mechanical properties and good corrosion resistance.

Monobloc

Manufactured in one piece as opposed to comprising a number of sub-members joined by bolting, welding, etc.

Monochromatic

Consisting of electromagnetic radiation having a single wavelength or an extremely small range of wavelengths, or particles having a single energy or an extremely small range of energies.

Monochromatic Objective

An *objective* in a microscope, usually a fused quartz, that has been corrected for use with monochromatic light only.

Monochromator

A device for isolating radiation of one or nearly one wavelength from a beam of many wavelengths.

Monoclinic

A crystal structure having three axes of any length, with two included angles equal to 90° and one included angle not equal to 90°. See also *unit cell*.

Monocoque

A form of construction in which all of the principal components carry their share of the applied load. For example, the bodywork of a monocoque vehicle is loadbearing rather than merely being carried by a substantial chassis.

Monofilament

A single fiber or filament of indefinite length that is strong enough to function as a yarn in commercial textile operation.

Monolayer

(1) The basic laminate unit from which cross-plyed or other laminate types are constructed. (2) A “single” layer of atoms or molecules adsorbed on or applied to a surface.

Monolithic

An object comprised entirely of one massive piece (although polycrystalline or even heterogeneous) as opposed to being built up of preformed units.

Monolithic Lining/Coating

A lining or coating in one piece formed by techniques such as pouring, spraying, or plastering rather than being built up from bricks or slabs. The terms are particularly applied to refractory applications.

Monolithic Refractory

A refractory that may be installed *in situ* without joints to form an integral structure.

Monomer

A single molecule that can react with like or unlike molecules to form a polymer. The smallest repeating structure of a polymer (mer). For addition polymers, this represents the original unpolymerized compound.

Monotectic

An isothermal reversible reaction in a binary system, in which a liquid on cooling decomposes into a second liquid of a different composition and a solid. It differs from a *eutectic* in that only one of the two products of the reaction is below its freezing range.

Monotropism

The ability of a solid to exist in two or more forms (crystal structures), but in which one form is the stable modification at all temperatures and pressures. *Ferrite* and *martensite* are a monotropic pair below the temperature at which *austenite* begins to form, for example, in steels. Alternate spelling is monotrophism.

Monte Carlo Technique

Calculation of the trajectory of incident electrons within a given matrix and the pathway of the x-rays generated during interaction.

Mordant

A substance used in dyeing for fixing the color (the word means *bitter*). A mordant must have an affinity for the material being dyed and be chemically reactive; that is, the molecule must have free electrons that combine with the dyestuff. The vegetable fibers, such as cotton and linen, frequently require mordants. Basic aniline dyes require a mordant for cotton or rayon, and the water-soluble acid dyes need a mordant for vegetable fibers. The mordant may be applied first, usually in a hot solution or simultaneously with the dye. *Mordant dyes* are dyes chemically able to accept and hold a metal atom, the metal being added in the mordant. The metal atom is held to the oxygen atoms and

to one of the nitrogen atoms in each chromophoric group of the dye, forming highly insoluble materials known as *lakes*.

Besides fixing the color, mordants sometimes increased the brilliance of the dye, particularly when chelation occurs. Common mordants are *alum* and *sodium bichromate*, but salts of aluminum and other metals are used. *Sodium stannate*, used both as a mordant and for fireproofing textiles, is a great-white, water-soluble powder made by treating tin oxide with caustic soda. *Chromium acetate*, used as a mordant for chrome colors and to produce khaki shades with iron solutions, is a grayish-green powder. It is soluble in water. In gilding, the term *mordant* is used to mean a viscous or sticky substance employed to make the gold leaf adhere, but such a material does not have the chemical action of a mordant.

Morphology

The characteristic shape, form, or surface texture or contours of the crystals, grains, or particles of (or in) a material, generally on a microscopic scale.

Mortar

A plastic mixture of cementitious materials, fine aggregates, and water in ratios of about 1:3:0:5 by mass.

Mosaic Crystal

An imperfect single crystal composed of regions that are slightly disoriented relative to each other.

Mosaic Structure

In crystals, a substructure in which adjoining regions have only slightly different orientations.

Mössbauer Effect

The process in which γ -radiation is emitted or absorbed by nuclei in solid matter without imparting recoil energy to the nucleus and without Doppler broadening of the γ -ray energy.

Mössbauer Spectroscopy

An analytical technique that measures recoilless absorption of γ -rays that have been emitted from a radioactive source as a function of the relative velocity between the absorber and the source.

Mössbauer Spectrum

A plot of the relative absorption of γ -rays versus the relative velocity between an absorber and a source of γ -rays.

Mother of Pearl

The hard, brilliant-colored internal layer of the *pearl oystershell* and of certain other marine shellfish. It is employed for knife handles, buttons, inlay work, and other articles. The iridescent appearance of the pearl oyster is due to the structure of the nacre coating, and the shells are also called *nacre*. Mother of pearl is brittle but can be worked with steel saws and drills using a weak acid lubricant. The shells are thick and heavy, and disks cut from them are split for buttons. A beautiful pink nacre occurs on the inner surface of the conch

M

shell; a sea snail that grows in great abundance off the Caicos Island near Haiti. There are about 56 species, and they grow up to 12 in. (30 cm) long and 8 in. (20 cm) wide. The shells were formally much used for making cameos. *Mussel shell*, from freshwater mussels of the Mississippi River, is also called *pearl shell*, but it does not have the iridescence of mother of pearl. There is a large production in Iowa, used for buttons. The waste shell from the manufacturer is crushed and marketed for poultry feed. *Pearl essence*, used for making *imitation pearls* and in plastics and lacquers, is a motley-silver compound extracted from the scales of fish, notably the sardines, herring, and alewife. Only a few types of fish have iridescent scales. The chief constituent is guanine, a chemical related to caffeine. *Synthetic pearl essence* may be ground nacreous shells in a liquid vehicle, or it may be produced chemically. Compounds of basic lead carbonate and lead mono-hydrogen phosphate have multiple reflectivity and give an optical effect resembling that of mother of pearl. *H-scale*, of Hoechst Celanese, and *Ko-Pearl*, of all Ultra Ray Pearl Essence Corp., are synthetic pearl essences.

Mottled Cast Iron

Iron that consists of a mixture of variable proportions of gray cast-iron and white cast iron; such a material has a mottled fracture appearance. It also has graphite flakes in some parts, but not in others.

Mounting

A means by which a specimen for metallographic examination may be held during preparation of a section surface. The specimen can be embedded in plastic or secured mechanically in clamps.

Mounting Artifact

A false structure introduced during the mounting stages of a metallographic surface-preparation sequence.

Mounting Resin

Thermosetting (e.g., Bakelite or diallyl phthalate) or thermoplastic (e.g., methyl methacrylate or polyvinyl chloride) resins used to mount metallographic specimens. Standard plastic mounts usually measure 25 mm (1 in.), 32 mm (1.25 in.), or 38 mm (1.5 in.) in diameter; mount thickness is approximately 1/2 the mount diameter.

M Shell

The third layer of electrons surrounding the nucleus of an atom, having electrons characterized by the principal quantum number 3.

MPa

MegaPascal. See *Pascal*.

MPI

Magnetic particle inspection.

M_s Temperature

For any alloy system, the temperature at which martensite starts to form on cooling. See *transformation temperature* for the definition applicable to ferrous alloys.

Mucilage

A sticky paste obtained from linseed and other seeds by precipitation from a hot infusion and used as a light adhesive for paper and as a thickening agent. It contains arabinose, glucose, and galactose, and it is easily soluble in water. Mucilage as a general name also includes *water-soluble gums* from various parts of many plants and has the same uses. It is the stored reserve food of plants. There are two types: the cell-content mucilage, which acts as a disorganization product of some of the carbohydrates, and membrane mucilage, which acts as a thickening agent to the cell wall. Membrane mucilage occurs in the acacias, algae (seaweeds), linum (flax plants), ulmus (elms), and astragalus. When it is collected in the form of exudations from the trees, it is called a gum. *Cherry gum* is this type of water-soluble gum, as is *medlar gum*, from a small tree of the same family as the cherry, grown in Europe and the Near East. See also *adhesive*, *glue*, *paste*, and *sizing*.

Muck Rolled Iron

See Puddling process.

Muffle Furnace

A common type of *sintering* furnace for continuous or discontinuous operation. The muffle may be ceramic to support electric heating elements or resistor wire windings, or may be a gas-tight metallic retort to retain the furnace atmosphere and support the work trays; both kinds may be used in the same furnace.

Mulling

The mixing and kneading of foundry molding sand with moisture and clay to develop suitable properties for molding.

Mullite

Artificial mullite, or synthetic mullite, a ceramic material made by a prolonged fusing in the electric furnace of a mixture of silica sand and diaphoric clay and bauxite, has the composition $3\text{Al}_2\text{O}_3 \cdot 2\text{SiO}_2$, has a melting point of 1810°C, and softens at 1650°C.

Mullite occurs in nearly all ceramic products containing alumina and silica but, with the exception of refractories, is seldom introduced as such except as calcined kyanite.

The bricks are resistant to flame and to molten ash, and they have a low, uniform coefficient of thermal expansion and a heat conductivity only slightly above that of fireclays. Normally, mullite has very fine crystals that change form and become enlarged after prolonged heating, making the product porous and permeable. For stable high-temperature refractories, the mullite is prefused to produce larger crystals. At very high temperatures, mullite tends to decompose to form corundum and alkali-silicate minerals of lower heat resistance. Mullite is also used for making spark plugs, chemical crucibles, and extruding dies, and a foamed mullite is used as a uniformly latticed honeycomb structure for lightweight, heat-resistant structural parts.

Multiaxial Stresses

- (1) Any stress state in which two or three principal stresses are not zero.
- (2) Any state in which more than one principal stresses are applied.

Multifilament Mesh

Woven material with multiple-strand threads.

Multifilament Yarn

A large number (500–2000) of fine, continuous filaments (consisting of 5–100 individual filaments) usually with some twist in the yarn to facilitate handling.

Multigrade Oil

An oil having relatively little change in viscosity over a specified temperature range.

Multiple

A piece of stock for forging that is cut from bar or billet lengths to provide the exact amount of material for a single workpiece.

Multiple Die Pressing

The simultaneous compaction of powder into several identical parts with a press tool consisting of a number of components.

Multiple Etching

Sequential etching of a microsection, with specific reagents attacking distinct microconstituents.

Multiple Punch Press

A mechanical or hydraulic press that actuates several punches individually and independently of each other.

Multiple Spot Welding

Spot welding in which several spots are made during one complete cycle of the welding machine.

Multiple-Impulse Welding

Spot, projection, or upset welding with more than one impulse of current during a single machine cycle. Sometimes called *pulsation welding*.

Multiple-Layer Adhesive

A dry-film adhesive, usually supported, with a different adhesive composition on each side; designed to bond dissimilar materials such as the core two-faced bond of a sandwich composite. See also *honeycomb* and *sandwich construction*.

Multiple-Pass Weld

A weld made by depositing filler metal with two or more successive passes.

Multiple-Screw Extruder

An extruder machine for processing thermoplastics that has two or four screws (conical or constant depth), in contrast to conventional single-screw extruders. Types include machines with intermeshing counter-rotating screws, intermeshing corotating screws, and nonintermeshing counter-rotating screws.

Multiple-Slide Press

A press with individual slides, built into the main slide or connected to individual eccentrics on the main shaft, that can be adjusted to vary the length of stroke and the timing. See also *slide*.

Multiplier Phototube

See *photomultiplier tube*.

Multiport Nozzle (Plasma Arc Welding and Cutting)

A constricting nozzle containing two or more orifices located in a configuration to achieve a degree of control over the arc shape.

Muntz Metal

Montz metal is a yellow brass containing—60% copper and 40% zinc; invented in 1832, it is also called yellow metal and malleable brass. Muntz metal is also modified with small amounts of iron and manganese. Iron above 0.35% forms a separate iron-rich constituent that is stable and gives hardness and high strength to the alloys. The addition of manganese helps to absorb the iron and also hardens the alloy. These alloys were also called high-strength brass and were employed for such uses as hydraulic cylinders and marine forgings, but are now largely replaced by manganese bronze or aluminum bronze.

Current standard wrought alloys are C28000 (59%–63% copper, as much as 0.30% lead, 0.07% iron, and the balance zinc); four leaded alloys—C36500, C36600, C36700, and C36800—each containing 58%–61% copper, 0.25%–0.70% lead, and as much as 0.15% iron and 0.25% tin, with the balance zinc except for 0.02%–0.06% arsenic in C36600, 0.02%–0.10% antimony in C36700, and 0.02%–0.10% phosphorus in C36800.

The alloys are available in most wrought forms, are hardenable only by cold working, and are used for forging parts, heat-exchanger tubing and tube sheets, baffles, valve stems, and fasteners. The corrosion resistance of C28000 is said to be generally similar to that of copper and better than that of higher-copper alloys to sulfur-bearing compounds.

Mushets Steel

The first (probably) steel developed for cutting at high temperature, that is, a high-speed steel; it was manganese deoxidized and probably had 1%–2% manganese with about 5%–10% tungsten and 2% carbon.

Music Wire

A high-grade, uniform steel originally intended for strings in musical instruments, but now employed for the manufacture of spiral springs. It is the highest grade of *spring wire* and is free from slag or dirt, and low in sulfur and phosphorus. For springs, it is usually *steel 1085* reduced about 80% in 8 or 10 drawing passes, but piano wire may have as many as 40 draws from a No. 7 rod. The tensile strength of spring wire, when hard drawn, is 225,000–400,000 lb/in.² (1551–2758 MPa), but it should be formable enough to bend 180° flat without cracking, or wind into a close helix with inside diameter 1–1.5 times the diameter of the wire. The smaller size of music wire is 0.003 in. (0.008 cm) in diameter. *Piano wire*, intended for piano strings but much used for springs, is a cold-drawing, high-quality

M

wire formerly only drawn from Swedish billets or rods but now made from U.S. steels.

Other spring steels and alloys include *austenitic stainless steels*, such as 302 and A286, and *iron-base superalloy*, containing about 25% nickel, 15% chromium, 2% titanium, 1.5% manganese, 1.25% molybdenum, 0.75% silicon, 0.3% vanadium, 0.08% maximum carbon, and not over 0.01% boron, and are used for springs in aircraft turbine engines. The tensile strength of the wire alloy reduced 30%

is 1365 MPa at 732°C. *Alloy 355*, for highly stressed springs and jet engines, has a nominal composition of 15.65% chromium, 4.38% nickel, 2.68% molybdenum, 1% manganese, 0.32% silicon, 0.12% copper, 0.124% nitrogen, and 0.142% carbon. See *piano wire*.

m-Value

See *strain-rate sensitivity*.

“N”-Type Semiconductor

See *semi* conductor.

N.A.M.A.S.

National Measurement Accreditation Service. The system for calibrating and certifying, measuring, and test equipment in the United Kingdom.

NaK

Sodium (Na) and potassium (K) alloy that is liquid at ambient temperature and so is used as a circulating coolant in some nuclear reactors.

Nanohardness Test

An indentation hardness testing procedure, usually relying on indentation force versus tip displacement data, to make assessments of the resistance of surfaces to penetrations of the order of 10–1000 nm deep. The prefix “nano-” normally would imply hardnesses 1000 times smaller than “microhardness”; however, the use of this prefix was primarily designed as a means to distinguish this technique from the more traditional microindentation hardness procedures. Most nanohardness testing procedures used three-sided pyramidal diamond indenters.

Nanophase Materials

Emerging materials, often multilayered in composite form, produced in building blocks so small as to be measured in nanos, or 10^{-9} units, and having superior physical or mechanical properties compared with your conventional, or “bulk,” counterparts. They are made by controlling the arrangement of matter on an atomic or molecular scale so as to create materials comprising particles or grains 39–3900 nm. (1–100 nm) wide or of layers or filaments of this thickness. Near-perfect materials, with critical flaw sizes less than the layer thickness, can be made, thereby creating materials approaching theoretical strengths. An early use, an extension of thin-film deposition, was in mirrors for soft x-rays.

Nanophase materials include metals, plastics, elastomers, carbon, and ceramics. The powder can be used in several ways: as a dispersion in fluid media, on supporting substrates, for consolidation into parts and forms, as a sintering aid, and as a feedstock for films and coatings. Among the applications are polishing slurries with nanoparticles of *alumina*, *silica*, and *cerium oxide*; titanium or *zinc oxide* particles in sunscreens for greater protection from ultraviolet rays; Fe_2O_3 pigments in cosmetics and silver or copper particles in *conductive polymers* and *inks*; *titanium oxide* and *tin oxide* films for gas sensors; nanostructured *tungsten carbide cobalt* tool bits for cutting and oil exploration; doped oxides for low-voltage displays; *silicon carbide* and *silicon nitride* engine parts; magnetic devices; and alumina and aluminum nitride infrared window applications. Sintering temperatures with nanopowders are typically several

hundred degrees less than with conventional powders. For electrically conductive polymers, the use of *silver* nanopowder rather than flake fillers reduces metal embrittlement and accommodates larger differences in thermal expansion.

As grain size gets smaller, metals tend to get harder, stronger, and tougher. *Danaloy DSC copper*, a *nanophase copper* from Ultram International, is more than twice as hard as pure, annealed, conventional copper and is about 90% as conductive. Nanophase *superplastic aluminum alloys* and *superplastic nickel–aluminum alloys* exhibit superplasticity at lower temperatures than the conventional superplastic alloys. *Nanograin tungsten carbide* is harder and more abrasion and crack resistant than micrograin material, can provide sharper cutting tools, and can be coated with cobalt or nickel. Nanodyne, Inc. uses a solution-spray conversion process to make tungsten carbide–cobalt powder, which can be used for hard facing by thermal spraying or for cutting tools. The process also can be used to produce *cermets*, such as *chromium carbide nickel* and *iron titanium carbide*, as well as *oxide-dispersion-strengthened (ODS) ceramics*.

Nanomers, from Nancor, Inc., are *montmorillonite* minerals surface treated with compatibilizing agents for dispersion in exfoliated form in nanoscale size in a resin matrix. In this form, the nanomer particles have a flexural sheet-like structure about 394 nm. (1 nm) thick and a length and width of 59 μm . (1.5 μm) and less. One grain has more than 1 million particles. *Nanomer 1.30 TC*, intended for use with *nylon 6* and designed for extrusion compounding, doubles heat-deflection temperature (HDT), especially of low-viscosity grades, and reduces gas permeability while increasing flame retardance. Nanoscale particles can also selectively hydrolyze polymers to form microcrystal polymers. Micro Poly Corp. has focused microcrystal *amylose*, *nylon*, and *polyester* on food and pharmaceutical products. The polyesters also aimed at replacing urea formaldehyde resins in making plywood and particle board. Other potential products are *dry lubricants*, *chelants*, *inks*, *dyes*, *conductive carbon* for electrodes, and *activated carbon*, the latter having 10 times the adsorptive surface of ordinary carbon. *Nanosilicate-coated high-density polyethylene* (HDPE) has greater barrier resistance to gasoline than HDPE alone. *Nanophase-clay* platelets in polymer-silicate-layered nanocomposites promise stronger polyester, polypropylene, and fluoropolymer packaging films of greater barrier resistance and flame retardance. *Silicon elastomer nanocomposites* containing 5% *fluorohectorite clay* are stronger and tougher than traditional silicone elastomers.

Carbon nanophase materials, also called *carbon nanotubes*, consist of a graphite sheet that has been rolled into a tube and having *fullerene* end caps. They contain millions of carbon atoms, each in an assigned place, and are only a few atoms in circumference. Their tensile strength is said to be at least 10 times that of traditional carbon fibers, making them the strongest of material in this respect. They are light in weight, quite rigid, and flexible and resilient normal to the tube surface or length, thus promising for reinforcements of *polymer–matrix composites* in aircraft and aerospace applications. *Carbon nanofibers* as small as 394 nm. (100 nm) diameter have been made from polyacrylonitrile as well as mesophase pitch by electrospinning.

Because of their fine size, they can provide a greater surface-area-to-mass ratio than the currently used 394 μm . (10 μm) fibers. *Pyrograf-III carbon*, from Pyrograf Products, is a vapor-grown *carbon nanofiber* made under license from General Motors. Because of their fineness, nanofiber-reinforced polymers can provide a Class A autobody panel finish, unlike the current carbon fibers that yield rougher finishes. Also, being electrically conductive, such composites can be electrostatically painted to such a finish.

Lengthwise, carbon nanotubes are about as electrically conductive as copper, though much less so transverse to length. At Samsung Advanced Institute of Technology (South Korea), they have been made into cathodes for field-emission color displays that require only half the power of *liquid crystal* displays. The nanotubes are as thermally conductive as diamond and behavior as metals or semiconductors. Changing their environment from oxygen to vacuum, changes molded from positive to negative, and the reaction is reversible.

Thus, the nanotubes can serve as diodes and transistors as well as oxygen sensors. Other potential uses are high-temperature catalyst supports, thermal-management devices, and electrostatic dissipation of various products. Hyperion Catalysis International offers resin masterbatches of *nylon*, *polybutylene terephthalate*, *polyethylene terephthalate*, *polycarbonate*, *polystyrene*, and *polyetheretherketone* containing 15%–20% “graphite fibrils,” or multiwall carbon nanotubes. Target applications include nylon auto fuel lines, computer disk drive components and chip trays, and handheld industrial bar scanners. General Electric Plastics’ nanotube-filled *Noryl GTX*, a *phenylene oxide-nylon alloy*, has been used for painted automirror housings and fuel filler caps and is a candidate for electrostatically painted fenders and other autopanel.

Many potential applications are also emerging for *nanoceramics*. Use of nanosize ceramic particles reduces sintering temperature and shrinkage during sintering and subsequent brittleness while increasing formability and machinability. Reaction-sintered formulations of equal amounts of very pure natural *dolomite* and synthesized *zirconia* doped with 0.5% by weight *lithium fluoride* are candidates for high-temperature filters. *Gallium oxide* nanoceramic sensors are intended for measuring air-fuel ratio in exhaust gas flow of advanced turbine engines. *Sialon* silicon nitride and alumina ceramic, modified with calcium, could be used in nanophase form for catalyst carriers and microfilters. Nanosize *FeS₂ powder*, formulated with eutectic salt and silicon oxide, is a candidate for thermal battery cathode disks. Nanosize *titanium dioxide* could be used in cosmetics, photochromic coatings, fibers, and, for better oxygen permeability, contact lenses.

At BIRL, the industrial research laboratory of Northwestern University, magnetron vacuum reactive sputtering has led to nanophase *composite coatings* twice as hard as either constituent material. Within alternating layers of columbium nitride titanium nitride and vanadium nitride titanium nitride, Vickers hardness values half that of diamond are achieved, portending potential applications for cutting tools and wear-resistant parts. Pratt and Whitney are exploring various metal/metal, metal/ceramic, and ceramic/ceramic coatings for greater heat, wear, or erosion resistance than conventional coatings can provide. In these combinations, ductile layers could mitigate cracking of hard and wear-resistant but brittle layers, or the various layers could be graded to better match the substrate’s coefficient of thermal expansion. *Dylyn coatings*, from Advanced refractory coatings, are diamond-like carbon-silicon coatings of low friction coefficient, extreme hardness, and high thermal stability.

Nanostructure

This is a material structure assembled from a layer or cluster of atoms with size on the order of nanometers. Interest in the physics of condensed matter at size scales larger than that of atoms and smaller than that of bulk solids (mesoscopic physics) has grown rapidly since the 1970s, owing to the increasing realization that the properties of these mesoscopic atomic ensembles are different from those of conventional solids. As a consequence, interest in artificially assembling materials from nanometer-sized building blocks, whether layers or clusters of atoms, arose from discoveries that by controlling the sizes in the range of 1–100 nm and the assembly of such constituents, it was possible to begin to alter and prescribe the properties of the assembled nanostructures. (Many examples of naturally formed nanostructures can be found in biological systems, from seashells to the human body.)

Nanostructured materials are modulated over nanometer length scales and zero to three dimensions. They can be assembled with modulation dimensionalities of zero (atom clusters or filaments), one (multilayers), two (ultrafine-grained overlayers or coatings or buried layers), and three (nanophase materials), or with intermediate dimensionalities. Thus, nanocomposite materials containing multiple phases can range from the most conventional case in which a nanoscale phase is embedded in a phase of conventional sizes, to the case in which all the constituent phases are of nanoscale dimensions. All nanostructured materials share three features: atomic domains (grains, layers, or phases) spatially confined to less than 100 nm in at least one dimension, significant atom fractions associated with interfacial environments, and interaction between their constituent domains.

Multilayers and Clusters

Multilayer materials have had the longest history among the various artificially synthesized nanostructures, with applications to semiconductor devices, strained-layer superlattices, and magnetic multilayers. Recognizing the technological potential of multilayered quantum heterostructure semiconductor devices helped to drive the rapid advances in the electronics and computer industries. A variety of electronic and photonic devices could be engineered utilizing the low-dimensional quantum states in these multilayers for applications in high-speed field-effect transistors antiefficiency lasers, for example. Subsequently, a variety of nonlinear optoelectronic devices, such as lasers and light-emitting diodes, have been created by nanostructuring multilayers.

Examples

Examples of nanostructured materials that have been characterized include multilayers, individual and assembled atom clusters, and cluster-consolidated nanophase materials.

Magnetic Multilayers

Magnetic multilayers, such as those formed by alternating layers of ferromagnetic iron and chromium, can be nanostructured so that the electrical resistance is significantly decreased (by up to a factor of 2 depending on the chromium layer thickness) by the application of a magnetic field. Such an effect, called giant magnetoresistance, occurs when the magnetic moments of the neighboring alternating layers are arranged in an antiparallel fashion so that application of the magnetic field overcomes the antiferromagnetic coupling and aligns the layers into a condition of parallel ferromagnetic ordering, strongly reducing the electron scattering in the system. Magnetoresistive materials have been introduced in the magnetic

recording industry as read heads because of their lower noise and improved signal-handling capabilities. Other nanostructured materials besides multilayers also exhibit giant magnetoresistance, such as magnetic cobalt clusters embedded in a nonmagnetic matrix of copper or silver, or magnetic plate-like nickel-iron deposits embedded in silver.

Optical Properties of Cluster Assemblages

Noninteracting assemblages of small semiconductor clusters have optical properties of both scientific and technological importance. The optical absorption behavior of cadmium sulfide clusters with diameters in the nanometer size regime made by any of a variety of methods, including chemical precipitation in solutions or in zeolite supports, is different from that for bulk cadmium sulfide.

Chemical Reactivity

Chemical reactivity of nanostructured materials, with their potentially high surface areas compared to conventional materials, can also be significantly altered and enhanced. Since clusters can be assembled by means of a variety of methods, there can be an excellent degree of control over the total available surface area and the resulting self-supported ensembles. Thus, it is possible to maximize porosity to obtain very high surface areas, remove most of it via consolidation but retain some to facilitate low-temperature doping or other processing, or fully densify the nanophase material.

Nanophase Materials

The assembly of larger atom clusters into bulk nanophase materials can also have dramatic effects upon properties. In this case, the clusters interact fully with one another, yet the effects of cluster size are still very important. Clusters of metals or ceramics in the size range of 5–25 nm have been consolidated to form ultrafine-grained polycrystals that have mechanical properties remarkably different and improved relative to their conventional coarse-grained counterparts.

Nanotechnology

This involves systems for transforming matter, energy, and information, based on nanometer-scale components with precisely defined molecular features. The term “nanotechnology” has also been used more broadly to refer to techniques that produce or measure features less than 100 nm in size; this meaning embraces advanced microfabrication and metrology. Although complex systems with precise molecular features cannot be made with existing techniques, they can be designed and analyzed. Studies of nanotechnology in this sense remain theoretical but are intended to guide the development of practical technological systems.

Basic Principles

Nanotechnology based on molecular manufacturing requires a combination of familiar chemical and mechanical principles in unfamiliar applications. In conventional chemistry, molecules move by diffusion and encounter each other in all possible positions and orientations. The resulting chemical reactions are accordingly hard to direct. Molecular manufacturing, in contrast, can exploit mechanosynthesis, that is, using mechanical devices to guide the motions of reactive molecules. By applying the conventional mechanical principle of grasping and positioning to conventional chemical reactions, mechanosynthesis can provide an unconventional ability to cause molecular changes to occur at precise locations in a precise sequence. Reliable positioning is required in order for

mechanosynthetic processes to construct objects with millions to billions of precisely arranged atoms.

Naphtha

A light, colorless to straw-colored liquid, which distills off from petroleum between 158°F and 194°F (70°C and 90°C). The specific gravity is from 0.631 to 0.660 or slightly higher, ranging from C_6H_{14} to C_7H_{18} . The lightest of the distillates used as solvents for fats, rubber, and resins approaches petroleum ether; the heaviest distillates approach benzene and gasoline and are used for fuel.

The name *naphtha* is also applied to heavier distillates from petroleum and to various grades of light oils obtained in the distillation of coal tar. They are widely used because of their low volatility and safety in handling. These include *solvent naphtha*, having a specific gravity of 0.862–0.872, with a boiling point below 320°F (160°C), and *heavy naphtha*, a dark liquid of specific gravity between 0.925 and 0.950 and boiling point between 320°F and 428°F (160°C and 220°C). *High-flash naphtha* for solvent purposes is a petroleum fraction with a specific gravity within the range of the gasolines. *VM&P*, or varnish maker's and painter's naphtha, is a specialty product that is available from Ashland Chemical, Inc. Various trade names are given to the light petroleum distillates used as solvents and in paints and harnesses such as Naphtholite.

At high temperatures, and in the absence of air, naphtha is cracked to ethylene, the most widely used commodity organic. In this application, naphtha is replacing ethane and propane as the choice of feedstock.

Naphthalene

Also called *tar camphor*. A white solid that is one of the heavy distillates from coal tar; it may also be obtained from petroleum. Naphthalene burns with a smoky flame and is soluble in benzene and in hot alcohol but not in water. Refined naphthalene comes in balls, flakes, and pellets, largely for use as an insect repellent, and most of the material is sold in technical grades for use in making dyestuffs, synthetic resins, coatings, tanning agents, and celluloid. The largest use is for production of phthalic anhydride. It is also the source of carbaryl, a *methyl carbamate* used extensively as a replacement for DDT. Union Carbide Corp.'s *Sevin* is such a product. *Naphthalene crystals* are very transparent to fluorescent radiation, and light produced in thick layers can escape and reach a photo surface. Low pulses can be obtained from the absorption of beta and gamma rays in naphthalene. It is thus used in photomultiplier tubes as a gamma-ray detector.

Napped Cloth

A woven metallurgical polishing cloth in which some fibers are aligned approximately normal to one of its surfaces.

Nascent Surface

A completely uncontaminated surface produced, for example, by cleavage fracture under ideal vacuum conditions.

National Bureau of Standards

The body in the United States responsible for establishing standards for scientific and technical data.

Native Metal

(1) Any deposit in the earth's crust consisting of uncombined metal. (2) The metal in such a deposit. (3) Metals found naturally in bulk and near pure form, including gold, silver, and copper. Sometimes, the term is extended to include extraterrestrial material such as meteorites.

Natural Aging

(1) Spontaneous aging of a supersaturated solid solution at room temperature. See also *aging*. Compare with *artificial aging*. (2) Generally, any time-related deterioration but more specific. See *precipitation hardening*.

Natural Cement

A *hydraulic cement* produced by calcining a naturally occurring argillaceous limestone at a temperature below the sintering point and then grinding to a fine powder.

Natural Diamond

The densest form of crystallized carbon and the hardest substance known, natural diamond occurs most commonly as well-developed crystals in volcanic pipes or in alluvial deposits. Bort sometimes refers to all diamonds not suitable for gems, or it may refer to off-color flawed or impure diamonds not fit for use for gems or most other industrial applications but suitable for the preparation of diamond grain and powder for use in lapping or the manufacture of most diamond grinding wheels. This type of bort is also called crushing bort or fragmented bort. See also *diamond* and *man-made diamond*.

Natural Draft

Taper on the sides of a forging, due to its shape or position in the die, that makes added *draft* unnecessary.

Natural Fiber

A natural fiber is one obtained from a plant, animal, or mineral. The commercially important natural fibers are those cellulosic fibers obtained from the seed hairs, stems, and leaves of plants; protein fibers obtained from the hair, fur, or cocoons of animals; and the crystalline mineral asbestos.

The natural fibers may be classified by their origin as cellulosic (from plants), protein (from animals), and mineral. The plant fibers may be further ordered as seed hairs, such as cotton; bast (stem) fibers, such as linen from the flax plant; hard (leaf) fibers, such as sisal; and husk fibers, such as coconut. The animal fibers are grouped under the categories of hair, such as wool; fur, such as angora; or secretions, such as silk. The only important mineral fiber is asbestos, which because of its carcinogenic nature has been banned from consumer textiles.

Natural Gas

Fuel gas obtained from natural subterranean sources and comprising a wide range of hydrocarbon gases.

Natural Rubber

Rubber is characterized as being a highly elastic or resilient material, and the natural product is obtained mainly as a latex from cuts in the trunks of the *Hevea brasiliensis* tree. The latex consists of small particles (averaging about 2500 Å units in diameter) of rubber suspended in an aqueous medium (and about 35% solids content). The system also contains about 6%–8% nonrubber constituents, some of which are emulsifiers, naturally occurring antioxidants, and proteins.

The rubber part of the composition, which is obtained from the latex by coagulation, washing, and drying, consists of long linear polymeric molecules of high average molecular weight. One report states that natural rubber contains molecules of molecular weights from 50,000 to 3,000,000 with 60% of it over 1,300,000. The rubber is built up of C_6H_8 units, each containing a double bond, and the overall structure is called *cis*-polyisoprene. Although a product almost identical to natural rubber has been made by polymerizing isoprene, there is no indication that a tree makes rubber from isoprene.

Vulcanization

Raw rubber as obtained from the latex is not useful directly in many commercial applications because of stiffening at low temperatures and softening at high temperatures. It must be vulcanized to give a wider temperature range for application and good physical properties. The most usual vulcanization is by the use of sulfur and organic accelerators of vulcanization in the presence of zinc oxide at temperatures in the neighborhood of 100°C–204°C depending on the curing system.

Also, for many applications, the high rubber vulcanizates are not tough enough for good service. To improve the situation, reinforcing fillers are used for compounding the rubber, such as finely divided carbon black, silica, and silicates including clays. In addition, many other nonreinforcing fillers, such as whiting (calcium carbonate) and barytes, are used to lower cost or to lend special properties to finished articles.

Environmental Effects

Under service conditions, natural rubber articles are subject to some deteriorating effects, and the rubber must be compounded to minimize these effects. For example, it is subject to deterioration by the action of oxygen, ozone, heat, and light and to fatigue cracking under dynamic conditions. Antioxidants are used in compounds to retard air and heat deterioration, and special chemicals are added to protect against light deterioration, as well.

Processing

Natural rubber is, for most applications, masticated and compounded on mills or in Banbury mixers; the masticated material is then passed through a tubing machine to form various articles or parts of articles that are then vulcanized at an elevated temperature in a mold or under other suitable conditions.

Natural rubber is furnished to fabricators in the form of large bales or as latex. The bale rubber comes in a number of different grades, which are priced according to quality. The latex is sold at different solids contents; the higher solids contents are preferred partly because of shipping costs from the plantations.

Applications

Natural rubber is used for making many types of articles. Because of its abrasion-resistant quality and low hysteresis in reinforced compounds, it is used in truck-tire tread stocks and in conveyor belts that are employed in conveying abrasive material such as coal, crushed rock, ore, and cinders. In large tires, it has found application in carcass compounds because of the tack and building qualities of the raw polymer. It has also been used in carcass compounds because of the low heat buildup (low hysteresis) of the carcass compound vulcanizate during severe service conditions in tire usage.

Some of the many other applications for natural rubber include waterproof clothing and footwear, and wire insulation, as well as mechanical goods and sundries, products such as hot-water bottles, surgical goods, rubber bands and thread, engine mounts, tank tread blocks, and gaskets, sound and vibration damping equipment, and road underlay. In fact, it can be used almost anywhere a highly resilient, elastic, durable material is required. A few applications in the latex field are (1) in making latex thread by coagulating a fine stream of latex compound coming from a nozzle and then vulcanizing it, (2) in making foam sponge such as mattresses by gelling and vulcanizing a foamed latex, (3) in tire cord dipping, (4) in making such articles as surgeon's gloves by the latex dipping method, and (5) in carpets where it is used as a backing material to provide anchorage of the yarns and to give dimensional stability.

Natural Strain

See *true strain*.

Naturally Bonded Molding Sand

A foundry sand containing sufficient bonding material as mined to be suitable for molding purposes.

Nature Print

A technique for revealing flow lines in forgings or other wrought material. The forging is sectioned, polished, and heavily etched. It is then thinly coated with ink and a print obtained by pressing paper against a surface. See also *sulfur print*.

N.D.T.T.

Nil Ductility Transition Temperature. See *impact test*.

NDE

See *nondestructive evaluation*.

NDI

See *nondestructive inspection*.

NDT

(1) See *nondestructive testing*. (2) Variation on the next item.

Near-Infrared Radiation

Infrared radiation in the wavelength range of 0.78–3 μm (7,800–30,000 $\text{\AA}$). See also *electromagnetic radiation* and *infrared radiation*.

Near-Net Shape

See *net shape*.

Neat Oil

Hydrocarbon oil with or without additives used undiluted. This term is used particularly in metal cutting to distinguish these fluids from soluble oils (emulsions).

Neat Resin

Resin to which nothing (additives, reinforcements, and so on) has been added.

Nebulizer

A device for converting a sample solution into a gas-liquid aerosol for atomic absorption, emission, and fluorescence analysis. This may be combined with a burner to form a nebulizer burner. See also *atomizer*.

Neck

The contact area between abutting particles in a powder compact undergoing sintering.

Neck Formation

The growth of interparticle contacts through diffusion processes during sintering.

Neck-in

In *extrusion coating* of plastics, the difference between the width of the extruded web as it leaves the die and the width of the coating on the substrate.

Necking

(1) The reduction in the cross-sectional area of a material in a localized area by uniaxial tension or by stretching. (2) The reduction in the diameter of a portion of the length of a cylindrical shell or tube. (3) Local reduction in diameter just prior to failure during tensile loading. It occurs when the rate of work hardening ceases to increase in proportion to the increase in strain. As a consequence, further deformation is confined to the neck, which thins until the available ductility is exhausted and the material fails. Also termed as *waisting*.

Necking Down

Localized reduction in area of a specimen during tensile deformation.

Necking Strain

Same as *uniform strain*.

Needle Bearing

A bearing in which the relatively moving parts are separated by long, thin rollers that have a length-to-diameter ratio exceeding 5.0.

N

Needle Blow

A specific *blow molding* technique in which the blowing air is injected into the hollow article through a sharpened, hollow needle that pierces the parison.

Needled Mat

A *mat* for reinforcing plastics formed of strands cut to a short length, then felted together in a needle loom with or without a carrier.

Needles

Elongated or rodlike powder particles with a high aspect ratio.

Neel Point

See *Neel temperature*.

Neel Temperature

The temperature below which spins in an antiferromagnetic material are ordered antiparallel so that there is zero net magnetic moment. Also known as *neel point*.

Negative Creep

A contraction in dimensions resulting from an alloy undergoing an order/disorder change. It has been reported in Nimonic components in service at about 550°C but is not a creep phenomenon, although it might be argued that the contraction increases the creep stress.

Negative Distortion

The distortion in a microscopic image that occurs when the magnification in the center of the field exceeds that in the edge of the field. Also termed as barrel distortion. In contrast with *positive distortion*.

Negative Eyepiece

An eyepiece in an optical microscope in which the real image of the object forms between the lens elements of the eyepiece.

Negative Ion

An ion that can be an atom, molecule, or radical that has gained one or more electrons and hence is negatively charged.

Negative Rake

Describes a tooth face and rotation whose cutting edge lags the surface of the tooth face. See the term *face mill*.

Negative Replica

A method of reproducing a surface obtained by the direct contact of the replicating material with the specimen. Using this technique, the contour of the replica surface is reversed with respect to that of the original. See also *replica*.

Neodymium

A metallic element, one of the rare earth group.

Neon

A gaseous element, one of the rare or noble group.

Neoprene Rubber

Except for polybutadiene and polyisoprene, neoprene is perhaps the most natural rubberlike of all, particularly with regard to dynamic response. Neoprenes are a large family of rubbers that have a property profile approaching that of natural rubber and with better resistance to oils, ozone, oxidation, and flame. They age better and do not soften on heat exposure, although high-temperature tensile strength may be lower than that of natural rubber.

These materials, like natural rubber, can be used to make soft, high-strength compounds. A significant difference is that, in addition to neoprene being more costly than natural rubber by the pound, its density is about 25% greater than that of natural rubber. Neoprenes do not have the low-temperature flexibility of natural rubber, which detracts from their use of low-temperature shock or impact applications.

General-purpose neoprenes are used in hose, belting, wire and cable, footwear, coated fabrics, tires, mountings, bearing pads, pump impellers, adhesives, seal windows and curtain wall panels, and flashing and roofing. Neoprene latex is used for adhesives, dip-coated goods, and cellular cushioning jackets.

Nernst Equation

An equation that expresses the exact *electromotive force* of a cell in terms of the activities of products and reactants of the cell. The Nernst equation is given by

$$E = E^0 - \frac{RT}{nF} \ln \frac{(\text{ox})}{(\text{red})}$$

where

E is the electrode potential

E^0 is the standard electrode potential

R is the gas constant (1.987 cal/K mol)

T is the absolute temperature (in K)

n is the number of moles of electrons transferred into a half-cell reaction

F is the Faraday constant ($F = 23,060$ cal/V equivalent)

(ox) and (red) are the activities of the oxidized and reduced species, respectively

Nernst Layer, Nernst Thickness

The diffusion layer or the hypothetical thickness of this layer is given by the theory of Nernst. It is defined by

$$i_d = nFD \left\{ \frac{(C_o - C)}{\delta} \right\}$$

where

i_d is the diffusion coefficient

C_o is the concentration at the electrode surface

δ is the Nernst thickness (0.5 mm in many cases of unstirred aqueous electrolytes)

Nesting

In reinforced plastics, the placing of plies of fabric such that the yarns of one ply lie in the valleys beneath the yarns of the adjacent ply. Also called *nested cloth*.

Net Positive Suction Head

The difference between total pressure and vapor pressure in a fluid flow expressed in terms of equivalent height of fluid, or "head," by the following equation:

$$\text{NPSH} = \left\{ \frac{P_0}{w} + \frac{V^2}{2g} - \frac{P_v}{w} \right\}$$

where

P_0 is the static pressure

P_v is the vapor pressure

V is the flow velocity

w is the specific weight of fluid

g is the gravitational acceleration

This quantity is used in pump design as a measure of the tendency for cavitation to occur at the pump inlet.

Net Section Stress

The nominal stress calculated from the total load divided by the total cross section. It makes no allowance for stress raisers or other sources of uneven distribution of stress.

Net Shape

The shape of a powder metallurgy part, casting, or forging that conforms closely to specified dimensions. Such a part requires no secondary machining or finishing. A near-net shape part can be either one in which some but not all of the surfaces are net or one in which the surfaces require only minimal machining or finishing.

Netting Analysis

The analysis of filament-wound structures that assumes that the stresses induced in the structure are carried entirely by the filaments and the strength of the resin is neglected and that assumes also that the filaments possess no bending or shearing stiffness and carry only the axial tensile loads.

Network Etching

Formation of networks, especially in *mild steels*, after etching in nitric acid. These networks relate to subgrain boundaries.

Network Structure

A metallic structure in which one constituent occurs primarily at the grain boundaries, partially or completely enveloping the grains of the other constituents.

Neutral Axis/Plane

The line or plane, in a component subject to a complex stress pattern, where stress passes through zero as it changes from positive to negative. For example, a symmetrical beam being bent from its

natural form has a tensile longitudinal stress at the bend exterior and a compressive longitudinal stress at the inner surface. At approximately mid-thickness the neutral axis has zero longitudinal stress.

Neutral Filter

A filter that attenuates the radiant power reaching the detector by the same factor at all wavelengths within a prescribed wavelength region. See also *filter*.

Neutral Flame

(1) A gas flame in which there is no excess of either fuel or oxygen in the inner flame. Oxygen from ambient air is used to complete the combustion of CO_2 and H_2 produced in the inner flame. (2) An oxyfuel gas flame in which the portion used is neither oxidizing nor reducing. See also *carburizing flame*, *oxidizing flame*, and *reducing flame*.

Neutral Flux

A flux that is neither acidic nor basic but is added to modify some physical characteristic particularly fluidity.

Neutral Oil

A lubricating oil obtained by distillation, not treated with acid or with alkali.

Neutralization Number

An ASTM number given to quenching oils that reflects the oil's tendency toward oxidation and sludging. See also *saponification number*.

Neutron

An elementary particle that has approximately the same mass as the proton, but no electric charge. Rest mass is 1.67495×10^{-27} kg. An unbound (extranuclear) neutron is unstable and β -decays with a half-life of 10.6 min. See *atom*.

Neutron Absorber

A material in which a significant number of neutrons entering combine with nuclei and are not reemitted.

Neutron Absorption

A process in which the collision of a neutron with a nucleus results in the absorption of the neutron into the nucleus with the emission of one or more prompt γ -rays, and in certain cases, emission of α -particles, protons, or other neutrons or fission of the nucleus results. Also known as *neutron capture*.

Neutron Activation Analysis

Activation analysis in which the specimen is bombarded with neutrons; identification is made by measuring the resulting radioisotopes. See also *activation analysis*.

N

Neutron Capture

See *neutron absorption*.

Neutron Cross Section

A measure of the probability that an interaction of a given kind will take place between a nucleus and an incident neutron; it is an area such that the number of interactions that occur in a sample exposed to a beam of neutrons is equal to the product of the cross section, the number of nuclei per unit volume in the sample, the thickness of the sample, and the number of neutrons in the beam that would enter the sample if their velocities were perpendicular to it. The usual unit is the barn (10^{-24} cm²). See also *barn*.

Neutron Detector

Any device that detects passing neutrons, for example, by observing the charged particles or γ -rays released in nuclear reactions induced by the neutrons or by observing the recoil of charged particles caused by collisions with neutrons.

Neutron Diffraction

The phenomenon associated with the interference processes that occur when neutrons are scattered by the atoms within solids, liquids, and gases.

Neutron Embrittlement

Embrittlement resulting from bombardment with neutrons, usually encountered in metals that have been exposed to a neutron flux in the core of the reactor. In steels, neutron bombardment is evidenced by a rise in the ductile-to-brittle *transition temperature*.

Neutron Flux

The number of neutrons passing through an area in a unit of time.

Neutron Radiography

Radiography that uses neutrons generated by a nuclear reactor, accelerator, or by certain radioactive isotopes to form a radiographic image of a test piece. The neutrons are detected by placing a conventional x-ray film next to a converter screen composed of potentially radioactive materials or next to a transfer screen composed of prompt emission materials, which convert the neutron radiation to other types of radiation more easily detected by the film.

Neutron Spectrometry

See *neutron spectroscopy*.

Neutron Spectroscopy

Determination of the energy distribution of neutrons. Scintillation detectors, proportional counters, activation foils, and proton recoil are used.

Neutron Spectrum

The distribution by energy of neutrons impinging on a surface, which can be measured by neutron spectroscopy techniques or sometimes from knowledge of the neutron source. See also *dosimeter*.

Newman Band/Line/Lamellae

A mechanical twin in ferrite, usually indicative of high strain rates. See *twins*.

Newton

The SI-derived unit of force, symbol N equivalent to kg m/s².

Newton's Laws of Motion

(1) A body will remain static or will maintain its motion in a straight line unless an external impressed force acts upon it. (2) The change of momentum occurs at a rate proportional to the impressed force and in the same direction as the force. (3) Action and reaction are equal and opposite.

Newtonian Fluid

A fluid exhibiting Newtonian viscosity wherein the shear stress is proportional to the rate of shear. Compare with *dilatant*, *rheopeptic material*, and *thixotropy*.

Nib

(1) A pressed, preheated, shaped, sintered, hot-pressed, Russ drilled, or finished compact. (2) A generic term for a piece of cemented carbide intended for use as a wire drawing die.

Nibbling

(1) Contour cutting of sheet metal by use of a rapidly reciprocating punch that makes numerous small cuts. (2) Cutting sheet by punching multiple small overlapping holes with a powered punch and die set reciprocating at high speeds.

Nichrome

A range of proprietary alloys, the most well known of which is 80% nickel and 20% chromium. The alloys have good high-temperature strength and oxidation resistance, while their electrical resistance is low and their temperature coefficient of electrical resistivity is high. They are used for electrical heating elements and furnace furniture for service up to about 100°C.

Nick Break Test

A tensile or bend test in which fracture is initiated in a notch. The term usually refers to tests of welds where fracture is directed through a particular weld zone.

Nickel Aluminide

Nickel aluminide (NiAl) is available commercially in powder form in various mesh sizes from granular material to an average particle size of a few micrometers. Nickel aluminide is fairly strong at room temperature with the modulus of transverse rupture values ranging from 204 to 952 MPa, depending on fabrication methods, while at 1000°C the corresponding values are approximately half the room temperature strength. Creep resistance at these temperatures is extremely poor. Thermal shock resistance is quite good.

Nickel aluminide can be formed by hot pressing or by cold pressing and sintering, but the former method produced by far the best results.

Excellent oxidation resistance and fairly good strength make this material of interest for turbine blading or other combustion chamber applications. It has impact resistance that is better than most ceramics, intermetallic compounds, and some cermets. NiAl is also resistant to attack by molten glass and red and white fuming nitric acids, which suggests possible uses in the glass-processing industry or in some high-temperature chemical processes.

Nickel and Alloys

A silvery white metal, nickel (Ni) has been used in alloy form with copper since ancient times. Nickel has a specific gravity of 8.902, a density of 8.902 g/cm³, and is magnetic up to 360°C. The metal is highly resistant to atmospheric corrosion and resists most acids, although it is attacked by oxidizing acids, such as nitric. Its principal use is as an alloying element to stainless steels and nonferrous metals. It is also used for electroplating.

There are several commercial high-purity nickels, containing at least 99% of the metal plus trace amounts of complying cobalt and small amounts of other elements, such as carbon, copper, iron, manganese, silicon, and sulfur. They find use in electronic and aerospace applications, chemical- and food-processing equipment, and for anodes and cathodes, caustic evaporators, and heat shields. Nickel 200, also known as commercially pure nickel, may contain as much as 0.15% carbon, 0.25% copper, 0.40% iron, 0.35% manganese, 0.35% silicon, and 0.01% sulfur.

It is especially resistant to caustics, high-temperature halogens and hydrogen halides, and salts but not to oxidizing halides or ammonium hydroxide. Because it is susceptible to temperature embrittlement by carbon precipitation, it is restricted to a maximum service temperature of 316°C. Nickel 201, is low-carbon (0.02% maximum) counterpart, can be used at higher temperatures. The cast grade, designated CZ-100, is recommended for use at temperatures above 316°C.

Nickel 270 is the highest purity grade, being at least 99.97% nickel and containing no more than 0.02% carbon, 0.005% iron, and 0.001% each of other ingredients. Although similar to the other nickels in general corrosion resistance, it may be more prone to sulfur embrittlement under some conditions.

At cryogenic temperatures, nickel alloys are strong and ductile. Several nickel-base superalloys are specified for high-strength applications at temperatures to 1093°C. High-carbon nickel-based casting alloys are commonly used at moderate stresses above 1204°C.

Dispersion-Strengthened Nickel

Dispersion-strengthened nickel, or DS nickel, contains about 2.2% thoria as the dispersion-strengthening phase and, thus, has also been called TD nickel. The thoria markedly increases high-temperature strength. Tensile strengths, about 483 MPa ultimate and 331 MPa yield at room temperature, are on the order of 117 MPa at 1093°C. The material also retains about 60% of its room temperature tensile modulus, about 138×10^3 MPa, at 1093°C. DS nickel has poor oxidation resistance and, thus, requires coating for sustained use at high temperatures, such as for aircraft-turbine components and furnace equipment. It has been alloyed with about 20% chromium to improve oxidation resistance but still may require coating for prolonged use at high temperatures.

Ferrous Alloys

The largest commercial application for nickel is as an alloying element in both ferrous and nonferrous alloys. In unhardened nonaustenitic steels, nickel has the effect of slightly strengthening ferrite and mildly improving corrosion resistance. In balanced combinations with small amounts of chromium and manganese; or chromium, molybdenum, and manganese; or molybdenum and manganese (AISI 3100, 3300, 4300, 4600, 4800, 8600, 8700, 9300, 9800 series), hardenabilities of steels are greatly increased. In carburizing steels (AISI 2300 and 2500 series), nickel is used to strengthen and toughen the core.

Nickel is a strong austenite stabilizer and with chromium is used to form the important AISI 300 series of nonmagnetic austenitic stainless steels. In these steels, chromium is the principal alloying element and is the element responsible for their excellent corrosion resistance. Nickel contributes to this corrosion resistance, but its primary function is to promote and retain an austenitic structure at all recommended temperatures of use and under most conditions of plastic deformation. The mechanical properties of an austenitic steel are generally much less adversely affected by moderately elevated temperatures and very low temperatures that are ferritic or martensitic steels. Wrought stainless steels (AISI listing) with chromium and nickel content up to 22% and 26%, respectively, and in some cases with the addition of molybdenum, have been designed for specific heat- and corrosion-resisting service over and above the standard 18-8 type. Some cast stainless steels with extremely high chromium and nickel contents (up to 28% chromium, 10% nickel and 17% chromium, 66% nickel) are used for severe corrosion or heat-resisting applications. Nickel is also widely used as a property-improving addition to cast iron and as one of the many alloying elements and some ferrous high-temperature, high-strength superalloys.

Magnetic Alloys

Nickel and iron form a series of alloys with thermal expansion and magnetic characteristics of commercial importance. The alloy of 36% nickel ("Invar") has a thermal coefficient of expansion of almost zero over a small temperature range. The addition of 12% chromium, in lieu of some of the iron, produces an alloy ("Elinvar") with an invariable modulus of elasticity over a considerable temperature range as well as a fairly low coefficient of expansion. Variations in the content of nickel and other metals have produced a large number of alloys with particular coefficients for specific applications such as geodetic tapes, balance wheels in watches, tuning forks, and glass-to-metal seals. The alloy with 78% nickel (Permalloy) and many modifications of this composition have very high magnetic permeabilities at low field strengths and find application in the electronics field. Nickel also plays an important role in permanent magnets of the Alnico type, which contain 14%–18% nickel plus aluminum, cobalt, and sometimes copper.

Nonferrous Alloys

The principal groups of nonferrous alloys are those of slightly alloyed nickel, nickel and copper, nickel and chromium, and the superalloys. The slightly alloyed nickels ("Duranickel," "Permanickel," E-nickel, electronic nickel, etc.) in most cases contain more than 94% nickel.

Duranickel 301, a precipitation-hardened, 94% nickel alloy, has excellent spring properties to 316°C. During thermal treatment, Ni₃AlTi particles precipitate throughout the matrix. This action enhances alloy strength. Corrosion resistance is similar to that of commercially pure wrought nickel.

Permanickel 300 is a high-nickel alloy, containing at least 97% nickel and small amounts of titanium and magnesium and most of the other elements found in high-purity nickels. It is used for high-strength parts in electrical and electronic applications. It has a tensile modulus of 207,000 MPa and, depending on form and condition, tensile yield strengths of 241–1034 MPa.

The aforementioned alloys retain much of the corrosion resistance and physical properties of nickel, but they are alloyed to make them heat treatable by age hardening, more resistant to a specific form of corrosion (manganese to reduce susceptibility to sulfur embrittlement), or to produce desirable electronic characteristics.

Wrought beryllium nickel containing 97.5% nickel, 2% beryllium, and 0.5% titanium is used for springs, switches, bellows, diaphragms, and small valves. The age-hardenable alloy provides tensile yield strengths of 310–1586 MPa, 896 MPa at 538°C and has good corrosion resistance in general atmospheres and to reducing media. Casting alloys, containing 2%–3% beryllium and also age hardenable, are about equally strong and are used for molds to form glasses and plastics and for metal-forming tools, aircraft fuel-pump impellers, and seal plates and aircraft engines.

Binary Nickel Alloys

The primary wrought alloys in this category are the Ni–Cu grades known as Monel alloy 400 (Ni–31%Cu) and K-500 (Ni–29%Cu), which also contain small amounts of aluminum, iron, and titanium. The Ni–Cu alloys differ from nickel 200 and 201 because their strength and hardness can be increased by age hardening. Although the Ni–Cu alloys share many of the corrosion characteristics of commercially pure nickel, their resistance to sulfuric and hydrofluoric acids and brine is better. Handling of waters, including seawater and brackish water, is a major application. Monel alloys 400 and K-500 are immune to chloride-ion stress-corrosion cracking, which is often considered in their selection.

Other commercially important binary nickel compositions are Ni–Mo and Ni–Si. One binary type, *Hastelloy alloy B-2* (Ni–28%Mo), offers superior resistance to hydrochloric acid, aluminum chloride catalysts, and other strongly reducing chemicals. It also has excellent high-temperature strength in inert atmospheres and in vacuum.

Cast nickel–copper alloys comprise a low and high silicon grade, M-35-1 and QQ-N-288, and Grades A and E (1.5% silicon) are commonly used in conjunction with wrought nickel–copper in pumps, valves, and fittings. A higher silicon grade, QQ-N-288, Grade B (3.5% silicon), is used for rotating parts and wear rings because it combines corrosion resistance with high strength and wear resistance. Grade D (4.0% silicon) offers exceptional galling resistance.

Two other binary cast alloys are ACI N-12M-1 and N-12M-2. These Ni–Mo alloys are commonly used for handling hydrochloric acid in all concentrations at temperatures up to the boiling point. These alloys are produced commercially under the trade names *Hastelloy alloy B* and *Chlorimet 2*.

Many chemical-resistant nickel alloys, both wrought and cast, are noted mainly for their resistance to chemicals that are aggressive toward other metals, and many of these also possess substantial strength at elevated temperature. Although trade names abound, the *Hastelloys* and the *Incolloys* and *Inconels* are probably the most well known. Many of these alloys are resistant to normally aggressive acids, such as hydrofluoric and sulfuric, as well as to acetic and phosphoric acids, mixed acids, chlorides, solvents, and high-temperature oxidation and, thus, are widely used for chemical-processing equipment.

Among the more common alloys and their principal ingredients are *Hastelloy B*, which contains 26%–30% molybdenum, 46% iron, 2.5% cobalt, and 1% chromium; *Hastelloy B-2*, which contains the same amount of molybdenum and chromium but only 1% iron and 1% cobalt; *Hastelloy C*, having 15%–18% molybdenum and about as much chromium 4%–7% iron, 3%–5% tungsten, and 2.5% cobalt; *Hastelloy C-4*, with molybdenum and chromium content similar to those of *Hastelloy C* but no more than 3% iron and 2% cobalt; *Hastelloy D*, 8.5%–10% silicon, 2%–4% copper, and as much as 2% iron, 1.5% cobalt, and 1% chromium; *Hastelloy G*, 21%–23% chromium, 18%–21% iron, 5.5%–7.5% molybdenum, 1.75%–2.5% columbium plus tantalum, 1.5%–2.5% copper, and as much as 2.5% cobalt; *Hastelloy S*, 14.5%–17% chromium, 14%–16.5% molybdenum, and as much as 3% iron and 2% cobalt; and *Hastelloy C-276*, 15%–17% molybdenum, 14.5%–16.5% chromium, 4%–7% iron, 3%–4.5% tungsten, and as much as 2.5% cobalt. *Incoloy 800*, although iron base, is often grouped with these alloys. It contains 46% iron, 32.5% nickel, and 21% chromium. Nickel-base (42%) *Incoloy 825* contains 30% iron, 21.5% chromium, 3% molybdenum, and 2.3% copper.

Hastelloy X, which provides substantial strength and oxidation resistance at temperatures to about 1204°C, contains 20%–23% chromium, 17%–20% iron, 8%–10% molybdenum, 0.5%–2.5% cobalt, and 0.2%–1% tungsten. Solution-treated rapidly cooled sheet has room temperature tensile properties of 786 MPa ultimate strength, 359 MPa yield strength, 43% elongation, and 197×10^3 MPa modulus. At 982°C, these properties are 155 MPa, 110 MPa, 45%, and 126×10^3 MPa, respectively. The alloy is widely used for gas-turbine parts and other applications requiring heat and oxidation resistance. Although mainly a wrought alloy, it also can be investment cast.

Ternary Nickel Alloys

Two primary wrought and cast compositions are Ni–Cr–Fe and Ni–Cr–Mo. Ni–Cr–Fe is known commercially as *Haynes alloys 214* and *556* and *Inconel alloy 600* and *Incoloy alloy 800*. *Haynes' new alloy No. 214* (Ni–16%Cr–2.5%Fe–4.5%Al–Y) has excellent resistance to oxidation to 1204°C and resists carburizing and chlorine-contaminated atmospheres. *Haynes alloy 556* (Fe–20%Ni–22%Cr–18%Co) combines effective resistance to sulfidizing, carburizing, and chlorine-bearing environments with good oxidation resistance, fabricability, and high-temperature strength. *Inconel alloys 600* (Ni–15.5%Cr–8%Fe) has good resistance to oxidizing and reducing environments. Intended for severely corrosive conditions at elevated temperatures, *Incoloy 800* (Ni–46%Fe–21%Cr) has good resistance to oxidation and carburization at elevated temperatures, and it resists sulfur attack, internal oxidation, scaling, and corrosion in many atmospheres.

A cast Ni–Cr–Fe alloy CY-40, known as *Inconel*, has higher carbon, manganese, and silicon contents than the corresponding wrought grade. In the as-cast condition, the alloy is insensitive to the type of intergranular attack encountered in as-cast or sensitized stainless steels.

Significant additions of molybdenum make Ni–Cr–Mo alloys highly resistant to pitting. They retain high strength and oxidation resistance at elevated temperatures, but they are used in the chemical industry primarily for their resistance to a wide variety of aqueous corrosives. In many applications, these alloys are considered the only materials capable of withstanding the severe corrosion conditions encountered.

In this group, the primary commercial materials are *C-276*, *Hastelloy alloy C-22*, and *Inconel alloy 625*. *Hastelloy alloy C-22*

(Ni–22%Cr–13%Mo–3%W–3%Fe) has better overall corrosion resistance and versatility than any other Ni–Cr–Mo alloy. Alloy C-276 (57%Ni–15.5%Cr–60%Mo) has excellent resistance to strong oxidizing and reducing corrosives, acids, and chlorine-contaminated hydrocarbons. Alloy C-276 is also one of the few materials that withstand the corrosive effects of wet chlorine gas, hypochlorite, and chlorine dioxide. Hastelloy alloy C-22, the newest alloy in this group, has outstanding resistance to pitting, crevice corrosion, and stress corrosion cracking. Present applications include the pulp and paper industry, various pickling acid processes, and production of pesticides and various agrichemicals.

Superalloys

There is a great variety of high-temperature, high-strength nickel alloys; these are called superalloys because of their outstanding strength, creep resistance, stress-rupture strength, and oxidation resistance at high temperatures. They are widely used for gas turbines, especially aircraft engines. Most of these alloys contain substantial chromium for oxidation resistance; refractory metals for solid-solution strengthening; small amounts of grain-boundary-strengthening elements, such as carbon, boron, hafnium, and/or zirconium; and aluminum and titanium for strengthening by precipitation of an Ni(Al, Ti) compound known as “gamma prime” during age hardening. Among the well-known wrought alloys are *D-979*; *GMR-235-D*; *IN 102*; *Inconel 625*, *700*, *706*, *718*, *722*, *X750*, and *751*; *MAR-M 200* and *421*; *René 41*, *95*, and *100*;

Udimet 500 and *700*; and *Waspaloy*. Cast alloys include *B-1900*; *GMR-235-D*; *IN 100*, *162*, *738*, and *792*; *M252*; *MAR-M-200*, *246*, and *421*; *Nicrotung*; *René 41*, *77*, *80*, and *100*; and *Udimet 500* and *700*. Some wrought alloys are also suitable for casting, primarily investment casting.

A third class of superalloys includes ODS alloys such as *IN MA-754* (Ni–20%Cr–0.6% yttria) and *IN MA-6000* (Ni–15%Cr–2%Mo–4%W–2.5%Ti–4.5%Al), which are strengthened by dispersions such as yttria coupled (in some cases) with gamma prime precipitation (MA-6000).

An additional dimension of nickel-base superalloys has been the introduction of grain-aspect ratio and orientation as a means of controlling properties. In some instances, grain boundaries have been removed. Wrought powder-metallurgy alloys of the ODS class and cast alloys such as *MAR M-247* have demonstrated property improvements due to grain morphology control by directional crystallization or solidification. Virtually all uses of the cast and wrought nickel-based superalloys are for gas-turbine components.

Specialty Nickel Alloys

In addition to the aforementioned families, there are specialty nickel alloys for glass sealing and other applications. A series of paramagnetic alloys, called *nitinol*, are intermetallic compounds of nickel and titanium rather than nickel–titanium alloys. The compound NiTi contains theoretically 54.5% nickel, but the alloys may contain Ti₂Ni and TiNi₃ with about 50%–60% nickel. The NiTi and nickel-rich alloys are paramagnetic, with a permeability value of 1.002, compared with the unity value of a vacuum. A 54.5% nickel alloy has a tensile strength of 758 MPa with the elongation of about 15% and hardness of Rockwell C 35. The alloys close to the NiTi composition are ductile and can be cold-rolled.

The nitinol, with nickel content ranging from 53% to 57%, are known as memory alloys because of their ability to “remember” or return to a previous shape upon being heated. This unusual behavior

stems from a diffusionless transformation of the alloy. These shape-memory alloys have excellent fatigue strength, and damping around room temperature is reported to be one of the highest ever measured in a metal.

Nickel Brass

A number of alloys of copper, nickel, and zinc are termed nickel brass. Nickel–silicon brass contains very small percentages of silicon, usually about 0.60%, which forms a nickel silicide, Ni₂Si, increasing the strength and giving heat-treating properties. Rolled nickel–silicon brass, containing 30% zinc, 2.5% nickel, and 0.65% silicon, has a tensile strength of 785 MPa. Imitation silver, for hardware and fittings, was a nickel brass containing 57% copper, 25% zinc, 15% nickel, and 3% cobalt. The bluish color of the cobalt neutralizes the yellow cast of the nickel and produces a silver-white alloy. *Silver* was a nickel brass containing 67.5% copper, 26% zinc, and 6.5% nickel, with sometimes a little cobalt. Nickel brasses of alloy are used where white color and corrosion resistance are desired.

Nickel Bronze

This is a name given to bronzes containing nickel, which usually replaces part of the tin, producing a tough, fine-grained, and corrosion-resistant metal. A common nickel bronze containing 88% copper, 5% tin, 5% nickel, and 2% zinc has a tensile strength of 330 MPa, elongation 42%, and Brinell hardness 86 as cast. When heat treated or age hardened, the tensile strength is 599 MPa, elongation 10%, and Brinell hardness 196. Small amounts of lead take away the age-hardening quality of the alloy and also lower the ductility. But small amounts of nickel added to bearing bronzes increase the resistance to compression and shock without impairing the plasticity. A bearing bronze of this nature contains 73%–80% copper, 15%–20% lead, 5%–10% tin, and 1% nickel.

Nickel Oxide

Two of the nickel oxides are useful as colorants in ceramics: (1) nickelous oxide or green nickel oxide, NiO, and (2) black nickel oxide, Ni₂O₃. At 400°C, it oxidizes to Ni₂O₃, and at 600°C is reduced back to NiO.

Nickel produces a bluish-violet color in potash glasses and a violet tending toward brown in soda glasses. Nickel rates as one of the more powerful colorants, since 1 part in 50,000 produces a recognizable tint.

Nickel oxide is sometimes used to decolorize potash glass. Nickel oxide and nickel silicate have an advantage over manganese dioxide for decolorizing purposes in that they are not as sensitive in changing oxidizing and reducing environments.

Nickel Silver

Nickel silver is a name applied to an alloy of copper, nickel, and zinc, which is practically identical with alloys known in the silverware trade as *German silver*. *Packfong*, meaning white copper, is an old name for these alloys. The very early nickel silvers contained some silver and were used for silverware.

Some three dozen standard wrought alloys (C 73150–C 79900) and for standard cast alloys (C 97300–C 97800) are designated nickel silvers. Depending on the alloy, copper content of wrought alloys ranges from 48% to 80% and nickel content from about 7% to 25%, with zinc (1%–5%) except for smaller quantities of other elements, mainly manganese, iron, and lead. The cast alloys range from

about 55% to 65% copper, 12% to 25% nickel, 2.5% to 21% zinc, 2% to 10% lead, with lesser amounts of other elements.

The most common alloy, nickel silver C 75200, nominally contains 65% copper and 18% nickel and, thus, is often referred to as nickel silver 65-18. The electrical conductivity of the alloy is about 6% that of copper, and its thermal conductivity is 33 W/(m K). Tensile properties for thin flat products in the annealed condition are about 414 MPa ultimate strength, 207 MPa yield strength, and 30% elongation. Cold working to the hard temper triples yield strength and markedly reduces ductility. Wire, which has similar tensile properties annealed, can be cold worked to still greater tensile strength. Modulus of elasticity in tension is 124,110 MPa. All the cast alloys are suitable for sand and investment casting and some also for centrifugal and permanent mold casting. The strongest of these alloys, nickel silver C 97800, has typical tensile properties of 379 MPa ultimate strength, 207 MPa yield strength, 15% elongation, and 131,000 MPa modulus. Applications for wrought alloys include hollowware and tableware, watch and camera parts, hardware, diary equipment, costume jewelry, nameplates, keys, fasteners, and springs. The cast alloys are used for fittings, valves, ornaments, pump parts, and marine equipment.

Over the years, nickel silvers have been known by a variety of names. *Benedict metal* originally had 12.5% nickel, with two parts copper to one part zinc, but the alloy used for hardware and plumbing fixtures contains about 57% copper, 2% tin, 9% lead, 20% zinc, and 12% nickel. The cast metal has a strength of 241 MPa with the elongation of 15%.

Nickel Steels

This is steel containing nickel as the predominant alloying element. The first nickel-steel armor plate, with 3.5% nickel, was known as *Harveyized steel*.

Nickel added to carbon steel increases the strength, elastic limit, hardness, and toughness. It narrows the hardening range but lowers the critical range of steel, reducing danger of warpage and cracking, and balances the intensive deep-hardening effect of chromium. The nickel steels are also of finer structure than ordinary steels, and then nickel retards grain growth. When the percentage of nickel is high, the steel is very resistant to corrosion. At high nickel contents, the metals are referred to as iron-nickel alloys or nickel-iron alloys. The steel is nonmagnetic above 29% nickel, and the maximum permeability is at about 78% nickel. The lowest thermal expansion is at 36% nickel. The percentage of nickel in nickel steels usually varies from 1.5% to 5%, with up to 0.80% manganese. The bulk of nickel steels contains 2% and 3.5% nickel. They are used for armor plate, structural shapes, rails, heavy-duty machine parts, gears, automobile parts, and ordnance.

The standard ASTM structural nickel steel used for building construction contains 3.25% nickel, 0.45% carbon, and 0.70% manganese. This steel has tensile strength of 586–689 MPa and a minimum elongation of 18%. An automobile steel contains 0.10%–0.20% carbon, 3.25%–3.75% nickel, 0.30%–0.60% manganese, and 0.15%–0.30% silicon. When heat treated, it has a tensile strength up to 551 MPa and an elongation of 25%–35%. Forgings for locomotive crank pins, containing 2.5% nickel, 0.27% carbon, and 0.88% manganese, have a tensile strength of 572 MPa, elongation 30%, and reduction of area 62%. A nickel-vanadium steel, used for high-strength cast parts, contains 1.5% nickel, 1% manganese, 0.28% carbon, and 0.10% vanadium. The tensile strength is 620 MPa and elongation 25%. *Univan steel* for high-strength locomotive castings is a nickel-vanadium steel of this type. *Unionalloy steel* is an abrasion-resistant steel; the federal specifications for 3.5% nickel

carbon steel call for 3.25%–3.75% nickel and 0.25%–0.30% carbon. This steel has a tensile strength of 586 MPa and elongation 18%. When oil quenched, a hot rolled 3.5% nickel medium-carbon steel, SAE steel 2330, develops a tensile strength up to 1516 MPa, and a Brinell hardness of 223–424, depending on the drawing temperature. Standard 3.5% and 5% nickel steels are regular products of the steel mills, although they are often sold under trade names. Steels with more than 3.5% nickel are too expensive for ordinary structural use. Steels with more than 5% nickel are difficult to forge, but the very high nickel steels are used when corrosion-resistant properties are required. *Nicloy*, used for tubing to resist the corrosive action of paper-mill liquors and oil-well brines, contains 9% nickel, 0.10% chromium, 0.05% molybdenum, 0.35% copper, 0.45% manganese, 0.20% silicon, and 0.09% max carbon. The heat-treated steel has a tensile strength of 758 MPa, with elongation 35%. The cryogenic steels, or low-temperature steels, for such uses as liquid-oxygen vessels, are usually high-nickel steels. ASTM steel A-353, for liquid-oxygen tanks at temperatures up to –196°C, contains 9% nickel, 0.85% manganese, 0.25% silicon, and 0.13% carbon. It has a tensile strength of 654 MPa with an elongation of 20%. A 9% nickel steel, for temperatures down to –196°C, contains 9% nickel, 0.80% manganese, 0.30% silicon, and not over 0.13% carbon. It has a minimum tensile strength of 620 MPa and an elongation of 22%.

Nickel Sulfate

Nickel sulfate is the most widely used salt for nickel-plating baths and is known in the plating industry as single nickel salt. It is easily produced by the reaction of sulfuric acid on nickel and comes in pea green water-soluble crystalline pellets of the composition $\text{NiSO}_4 \cdot 7\text{H}_2\text{O}$, of a specific gravity of 1.98, melting at about 100°C. Double nickel salt is nickel ammonium sulfate, used especially for plating on zinc. To produce a harder and whiter finish in nickel plating, cobaltous sulfamate, a water-soluble powder, is used with the nickel sulfate. Nickel plate has a normal hardness of Brinell 90–140, but by controlled processes, file-hard plates can be obtained from sulfate baths. In the electroless plating, nickel sulfate, a reducing agent, a pH adjuster, and complexing and stabilizing agents are combined to deposit metallic nickel on an immersed object. The electroless nickel coating is comparable to electrolytic chrome.

Nickel-Bonded Titanium Carbide

This is a hard, strong material that retains its strength at temperatures up to 1100°C. It is most commonly used in the so-called cermet materials for high-temperature structural applications.

Nickel-bonded titanium carbide is available in powder form. Nickel-bonded titanium carbides have hardnesses ranging from HRA 80 to 89, depending on binder content. The melting point is that of the binder material, and the density is 5.0 g/cm³ min but can be higher depending on the amount and nature of the binder material.

Nickel-bonded titanium carbide is usually made by cold-pressing and sintering methods, but it can be hot pressed and, if the binder content is very high, it can even be cast.

The material may be used for turbine blading, and such high-temperature structural applications as tool bits, and as a high-temperature bearing and seal material, where high compressive strength, low coefficient of friction, and high wear resistance are needed at elevated temperatures. Oxidation resistance of these materials is fair and can be improved somewhat by adding niobium or tantalum carbide to the hard phase or by adding cobalt or chromium to the nickel binder.

Nickel–Chromium Steel

This is defined as steel containing both nickel and chromium, usually in a ratio of 2–3 parts nickel to 1 part chromium. The 2:1 ratio gives great toughness, and the nickel and chromium are intended to balance each other and physical effects. The steels are especially suited for large sections that require heat treatment because of their deep and uniform hardening. Hardness and toughness are the characteristic properties of these steels. Nickel–chromium steel containing 1%–1.5% nickel, 0.45%–0.75% chromium, and 0.38%–0.80% manganese is used throughout the carbon ranges for case-hardened parts and for forgings where high tensile strength and great hardness are required. Low nickel–chromium steels, having more carbon (0.60%–0.80%), are used for drop-forging dies and other tools.

Nickel–chromium steels may have temper brittleness or low impact resistance when improperly cooled after heat treatment. A small amount of molybdenum is sometimes added to prevent this brittleness. A nickel–chromium coin steel, used by the Italian government for coins, was a stainless steel type containing 22% chromium, 12% nickel, and some molybdenum.

Low-carbon nickel–chromium steels are water hardening, but those with appreciable amounts of alloying elements require oil quenching. Air-hardening steels contain up to 4.5% nickel and 1.6% chromium but are brittle unless tempered in oil to strengths below 1378 MPa. The alloy known as *Krupp analysis steel* contains 4% nickel and 1.5% chromium.

Nickel–Molybdenum Steel

This alloy steel is mostly used in compositions of 1.5% nickel and 0.15%–0.25% molybdenum, with varying percentages of carbon up to 0.50%. The steels are characterized by uniform properties and are readily forged and heat treated. Molybdenum toughens the steels and, in the case-hardening steels, gives a tough core. Roller bearings are made of this class of steel. Superalloy steel is 3160 steel. A 5% nickel steel with 0.30% carbon and 0.60% molybdenum has a tensile strength of 1206–1585 MPa with the elongation of 12%–22%, depending on the heat treatment. Molybdenum is more frequently added to the steels containing also chromium, the molybdenum giving air-hardening properties, reducing distortion, and making the steels more resistant to oxidation.

Nicol Prism

A prism used in optical microscopes made by cementing together with Canada balsam, two pieces of a diagonally cut calcite crystal. In such a prism, the ordinary ray is totally reflected at the calcite/cement interface, while the orthogonally polarized extraordinary ray is transmitted. The prism can thus be used to polarize light or analyze the polarization of light.

Nicrosilal

A proprietary, austenitic, growth-resistant cast iron with about 18% nickel, 5% chromium, 5% silicon, and only 2% carbon.

Nihard

A proprietary white cast iron with about 3% carbon, 4% nickel, 2% chromium, 0.5% silicon, and 0.5% manganese. It has a high hardness, about 600 Hv, but poor toughness and is used for grinding balls and rings, etc.

Ni-Hard

See *Nihard*.

Nil Ductility Transition Temperature

See *impact test*.

Nimocast

See *nimonic*.

Nimonic

A range of proprietary alloys, and cast or wrought form, based on nickel with major additions of other elements, in particular chromium, typically about 20%, with aluminum and titanium plus in some cases cobalt, molybdenum, etc. These alloys have good high-temperature characteristics and particular resistance to oxidation and good creep strength. The nimocast materials are similar materials in the cast form.

Niobium and Alloys

Note should be made of the fact that in the United States, this element was originally called columbium (symbol Cb). The Nomenclature Committee of the International Union of Pure and Applied Chemistry in 1951 adopted a recommendation to name this element niobium (symbol Nb). American chemists use this name, but the metallurgists and metals industries still use the name columbium. Most niobium is used in special stainless steels, high-temperature alloys, and superconducting alloys such as Nb₃Sn. The low cross-section capture of niobium for thermal neutrons of only 1.1 barn makes it suitable for use in nuclear piles.

Niobium is a tough, shiny, silver-gray, soft, ductile metal that somewhat resembles stainless steel in appearance. Niobium is relatively low density, yet can maintain its strength at high temperatures. It has excellent corrosion resistance to liquid metals and can be easily fabricated into wrought products.

Over 95% of all niobium is used as additions to steel and nickel alloys for increasing strength. Only 1%–2% of niobium is in the form of niobium-based alloys or pure niobium metal. Superconducting niobium–titanium alloys account for over half of that, and high-temperature and corrosion applications account for the remainder.

The density of niobium at 8.57 g/cm³ is moderate compared with most other high-melting-point metals. It is less than molybdenum at 10.2 g/cm³ and half that of tantalum at 16.6 g/cm³.

Alloys

Commercial niobium alloys are relatively low in strength and extremely ductile and can be cold worked over 70% before annealing becomes necessary. The resulting ease of fabrication into complex parts combined with relatively low density frequently favors the selection of niobium alloys over other refractory metals, such as molybdenum, tantalum, or tungsten.

High-temperature niobium alloys were developed in the 1960s for nuclear and aerospace applications and today serve in communications satellites, human body imaging equipment, and a variety of high-temperature components. Although niobium alloys have useful strength at temperatures hundreds of degrees above nickel-based

superalloys, applications have been limited by their susceptibility to oxidation and too long-term creep.

Production

Typical production electron beam furnaces generate 500–5000 kW of power and are capable of purifying ingots with diameters of 305–508 mm and weights over 2 m. “Drip-melting” is the current standard electron beam method, but hearth melting may eventually become practical as higher-power furnaces are developed.

Alloys of niobium are made by vacuum-arc remelting with the appropriate elemental additions. The most common alloying additions are zirconium, titanium, and hafnium, which readily go into solution during arc melting.

Properties

The most common high-temperature niobium alloys are all hardened and primarily by solid-solution strengthening; however, small amounts of second-phase particles are present. The composition of these particles varies, but they are generally associated with interstitial impurities that form oxides, nitrides, and carbides. These particles are important because the size and distribution of second phases can often have a strong influence on mechanical properties and recrystallization behavior. For example, a variation of the Nb–1%Zr alloy, commonly known as PWC-11, contains an intentional addition of 0.1 wt% carbon, specifically to form carbide precipitates that significantly improve high-temperature creep properties.

Another alloy, WC-3009, normally contains ~0.10 wt% oxygen, which is approximately five times more oxygen than other niobium alloys. This high level of oxygen, which is introduced during powder processing, is not deleterious to mechanical properties because the oxygen combines with hafnium in the alloy to form stable hafnium oxide precipitates. The WC-3009 alloy is unique in that it exhibits an oxidation rate less than 1/10 that of most other niobium alloys. When WC-3009 was developed, it was speculated that such an alloy could survive a short supersonic mission even if its protective coating failed.

In general, niobium alloys are much less tolerant of impurity pickup than other reactive metals such as titanium and zirconium. Alloys containing second-phase particles that form a continuous boundary between grains can exhibit drastically reduced tensile elongation. This condition is usually caused by contamination or improper heat treatment. Copper, which can accidentally be introduced during welding, is particularly disastrous to mechanical properties. In fact, the total permissible interstitial oxygen, hydrogen, carbon, and nitrogen content of niobium alloys is typically 1/5–1/10 that of titanium or zirconium alloys.

All of the commercial alloys are quite ductile at room temperature. The highest tensile strength at room temperature and elevated temperature are exhibited by the WC-3009 alloy. Even though WC-3009 clearly exhibits the highest tensile strength, FS-85 has superior creep strength. Its high creep strength is due to its higher melting point, which is elevated by its high concentration of tantalum and tungsten.

Elastic modulus, thermal conductivity, coefficient of thermal expansion, and total hemispherical emissivity are properties given in Tables N.2 and N.3 in *Adv. Mater. Proc.*, 154(6), 27–31, 1998 as well as tensile properties of the common alloys at 20°C. The emissivity data are for smooth and nonoxidized surfaces, which exhibit much lower emissivity values than oxidized material. Also shown is an emissivity value of 0.7–0.824 silicide-coated C-103. This value is for a common Si–20%Fe–20%Cr coating applied by the “slurry coat and fusion” method.

Applications

The most common application for niobium alloys is in sodium vapor lamps. The Nb–1%Zr alloy demonstrates excellent formability, weldability, and long life in a sodium vapor environment.

These bulbs are used throughout the world for highway lighting, because of their high electrical efficiency and long life, which is typically in excess of 25,000 h. The high-carbon version of this alloy, PWC-11, has a creep rate approximately five times lower than that of Nb–1%Zr at 1100°C, because of the effects of carbide precipitates.

For aerospace applications at 1100°C–1500°C, alloy C-103 has been the workhorse of the niobium industry because of its higher strength. Excellent cold-forming and welding characteristics enable fabricators to construct very complex shapes, such as thrust cones and high-temperature valves. Closed die forgings are also easily produced. Most of these components and propulsion systems are exposed for relatively short times to temperatures between 1200°C and 1400°C.

The service environment for propulsion systems often is less oxidizing than the normal atmosphere. Because C-103 has virtually no oxidation resistance, components are extensively coated with silicides.

Another very successful application for coated C-103 is thrust augmentor flaps in a turbine engine. These flaps, placed at the tail end of the engine to form a high-temperature liner in the afterburner section, typically reach 1200°C–1300°C and last for ~100 h of afterburner time.

Niobium alloys have also been evaluated for various high-temperature components of the National Aerospace Plane. Hypersonic leading edges and nose cones were fabricated to function as heat-pipe thermal management systems. The heat-pipe concept was designed to transport extreme heat away from hot spots, such as hypersonic leading edges, to cooler areas where heat could be expelled by radiation. A typical 500 g niobium heat pipe can dissipate over 10 kW of heat and operate isothermally at 125°C–1350°C. These devices were successfully tested in combustion torches, high-velocity jet fuel burners, tungsten–quartz lamps, and even electric welding arcs and heat flux as well over 1000 W/cm².

Nip

In a bearing, the amount by which the outer circumference of a pair of bearing shells exceeds the inner circumference of the housing. Also known as *crush*.

Nip Angle

See *angle of bite*.

Niresist

A proprietary, austenitic, corrosion resistant, cast iron with about 15% nickel, 2% chromium, and a percentage of copper.

Ni-Resist

See *Niresist*.

Nital

Nitric acid (2% unless otherwise stated) in alcohol for etching steels.

Nitinol

A proprietary alloy of 55% nickel and 45% titanium with shape-memory characteristics.

Nitralloy

A proprietary range of steels designed for nitriding and containing aluminum, chromium, and/or molybdenum in the 1% or so range.

Nitric Acid

Also called aqua fortis and azotic acid, nitric acid is a colorless to reddish fuming liquid of the composition HNO_3 , having a wide variety of uses for pickling metals, etching, and in the manufacture of nitrocellulose, plastics, dyestuffs, and explosives. It has a specific gravity of 1.502 (95% acid) and a boiling point of 86°C and is soluble in water. Its fumes have a suffocating action, and it is highly corrosive and caustic. Fuming nitric acid is any water solution containing more than 86% acid and having a specific gravity above 1.480. Nitric acid is made by the action of sulfuric acid on sodium nitrate and condensation of the fumes. It is also made from ammonia by catalytic oxidation or from the nitric oxide produced from air.

Nitride–Carbide Inclusion Types

A compound with the general formula $M_x(\text{C},\text{N})$, observed generally as colored idiomorphic cubic crystals, where M includes titanium, niobium, tantalum, and zirconium.

Nitrides

Nitrides are less stable than the oxides, carbides, and sulfides, and their use in air at elevated temperature is limited because of their tendency to oxidize. However, in several instances, the oxide film is protective and deterioration is slow. Despite their limitations, nitrides have interesting properties and are sure to find many specialized uses as technology becomes more complex.

Stable Nitrides

Aluminum Nitride

Aluminum nitride is conveniently prepared by an electric arc between aluminum electrodes in a nitrogen atmosphere. Crucibles of the pressed powder, and sintered at 1985°C , are resistant to liquid aluminum at 1985°C , to liquid gallium at 1316°C , and to liquid boron oxide at 1093°C . Aluminum nitride has good thermal shock resistance and is only slowly oxidized in air (1.3% converted to Al_2O_3 and 30 h at 1427°C). It is inert to hydrogen at 1705°C but is attacked by chlorine at 593°C .

Aluminum nitride is an excellent substrate for creating wide bandgap semiconductors for wireless communications and power industry applications. Since aluminum nitride is stable at very high temperatures, this substrate material can be used for microelectronic devices on jet engines. Such substrates could also improve the production of blue and ultraviolet lasers, which are used to squeeze a full-length movie onto a CD. Aluminum nitride crystals have also been grown in a tungsten crucible at 2300°C .

Boron Nitride

The crystal structure of boron nitride is similar to that of graphite, giving the powder the same greasy feel. The platy habit of the

particles and the fact that boron nitride is not wet by glass favor the use of the powder as a mold wash, for example, in the fabrication of high-tension insulators. It is also useful as thermal insulation in induction heating.

Boron nitride can be hot pressed to strong ivory-white bodies that are easily machined. Hot-pressed boron nitride is stable in air to about 704°C . From 704°C to 982°C , the rate of oxidation increases moderately. It is also stable in chlorine up to 704°C . However, at 982°C , it is attacked rapidly.

Like commercial graphite, hot-pressed boron nitride is anisotropic. Thermal expansion parallel to the direction of pressing is 10 times than in the perpendicular direction. The ratio for modulus of rupture is 2:1.

Although boron nitride resembles graphite in many respects, it differs uniquely and electrical characteristics, having high resistivity and high dielectric strength even at elevated temperatures. This feature, combined with easy machinability, has led to extensive use in high-temperature electronics.

Boron nitride is available as –325-mesh powder.

A cubic form of boron nitride (Borazon) similar to diamond in hardness and structure has been synthesized by the high-temperature, high-pressure process for making synthetic diamonds. Any uses it may find as a substitute for diamonds will depend on its greatly superior oxidation resistance.

Cutting tool materials like mixed ceramics or CBN cutting tools are already available for hard machining. To identify the proper cutting tool material, one must analyze the application.

In case of cutting interruptions, CBN cutting tools will be the appropriate choice. Continuous cuts allow the use of mixed ceramics or coated mixed ceramics for better efficiency. When producing a gear wheel, for example, turning with a CBN-tipped insert reduces the cost per wheel by more than 60%, compared to grinding. At the same time, disposal costs for grinding sludge vanish, because hard turning does not require coolant.

Silicon Nitride

Silicon nitride is most easily prepared by direct reaction of nitrogen at about 1316°C with finely divided elemental silicon (≤ 150 mesh), either as loose powder or as a slip-cast or otherwise preformed part. Conversion of silicon particles to the nitride Si_3N_4 is accompanied by the growth of a felt of interlocking needles in the void space between particles. Despite an overall porosity of 15%–25%, silicon nitride bodies are effectively impervious in many applications because of the microscopic size of the pores.

Although silicon nitride is not machinable in its final form except by grinding, the partially converted body can be machined by conventional methods after which conversion can be completed without dimensional change.

Silicon nitride is indefinitely resistant to air oxidation up to 1649°C but begins to sublime at about 1925°C . It is not attacked by chlorine at 899°C or hydrogen sulfide at 982°C nor by the common acids. Because of a low coefficient of thermal expansion, resistance to thermal shock is relatively good.

Uncoated and coated silicon nitride cutting tools dominate the high-performance end of gray cast iron machining. They typically offer metal removal rates at least three times higher than coated carbide grades.

The newly developed cutting tool combines a 6% cobalt substrate with a $10\text{ }\mu\text{m}$ thick, medium-temperature $\text{TiCN}/\text{Al}_2\text{O}_3/\text{TiN}$ coating. Medium-temperature chemical vapor deposition TiCN coatings show a reduced tendency for the forming of ϵ phase at the interface between coating and carbide substrate.

Silicon nitride cutting tools have a substantially improved fracture resistance. Because of their insufficient chemical wear

resistance, they have a limited use in machining nodular cast irons, mainly in areas of severe cutting interruptions at higher speeds (>400 m/min).

Titanium and Zirconium Nitride

Titanium and zirconium nitrides for use in refractory bodies are most conveniently prepared by treating the corresponding metal hydrides with ammonia at 1000°C .

Sintered TiN can be heated to a bright red heat with only superficial oxidation and then plunged into water without cracking; ZrN is less resistant to oxidation.

Combination coatings involving both chemical vapor deposition and physical vapor deposition technologies provide the wear-resistance advantages of chemical vapor deposition TiCN coatings with the compressive residual stress advantages of physical vapor deposition TiN coatings. The net result is improved wear and chipping resistance. These coatings increase the speed capabilities of carbide cutting tools and titanium turning by a factor of 2.

Eliminating coolants can turn an easy-to-machine material into a difficult drilling problem, when using standard cutting tools. The introduction of TiAlN coatings represents a significant step toward dry drilling.

The goal in all dry machining is to develop cutting tools with higher resistance to thermal load and fatigue. Cermet tools may be one of the most suitable materials for these applications.

Nitriding

Introducing nitrogen into the surface layer of a solid ferrous alloy by holding at a suitable temperature (below A_{c1} for ferritic steels) in contact with a nitrogenous material, usually ammonia or molten cyanide of appropriate composition. Quenching is not required to produce a hard case. See also *aerated bath nitriding*, *bright nitriding*, and *liquid nitriding* and *case hardening*.

Nitriding Steels

Nitriding steels are alloy steels (low- and medium-carbon steels with combinations of chromium and aluminum or nickel, chromium, and aluminum) design particularly for optimum results when they are subjected to the nitriding operation. The composition is such that the required microstructure for optimum nitriding is produced after heat treatment. Nitrided parts made from nitriding steels have extremely high surface hardness of about 92–95 Rockwell N scale, wear resistance, and resistance to certain types of corrosion.

Processing and Applications

Nitriding consists of exposing steel parts to gaseous ammonia at about 538°C to form metallic nitrides at the surface. The hardest coatings are obtained with the aluminum-bearing steels. Nitriding of stainless steel was known as Malcomizing. The nitride layer also has considerable resistance to corrosion from alkalies, the atmosphere, crude oil, natural gas, combustion products, tap water, and still saltwater. Nitrided parts usually grow about 0.003–0.005 cm during nitriding. The growth can be removed by grinding or lapping, which also removes the brittle surface layer. Most uses of nitrided steels are based on resistance to wear. The steels can also be used at temperatures as high as 538°C for long periods without softening. The slick, hard, and tough nitrided surface also resists seizing, galling, and spalling. Typical applications are cylinder liners and barrels for aircraft engines, bushings, shafts, spindles, and thread guides,

cams, rolls, piston pins, rubber and paper-mill products rolls, special oil tool equipment, bearings, rollers, etc.

Fabrication

The fabrication characteristics of nitriding steels are basically the same as those of other steels of similar alloy content. They can be drilled, broached, tapped, milled, sawed, or ground.

Light feeds and depth of cuts are recommended. Welding is done with rod or wire of similar composition. Flash welding is permissible.

If very heavy cuts are involved, they usually are made prior to heat treatment. Normal machining is done on heat-treated material and is followed by a stress-relieving treatment of not less than 37.8°C above the nitriding temperature, before finish machining or grinding. It is essential that in machining, sufficient removal be allowed to remove all decarburization from the surface prior to nitriding. The surface also must be clean and free of any surface contamination.

Because nitriding is a low-temperature treatment, little or no warpage is encountered. If it is necessary to straighten because of residual stress, the part should be heated to 538°C – 593°C to prevent surface cracking.

Nitrided parts normally grow about 0.03–0.05 mm during nitriding. This may be removed by grinding or lapping. This also has the advantage of removing a brittle layer on the surface and exposes a slightly harder layer immediately beneath it. This operation, however, will reduce corrosion resistance to a large degree.

Nitriding steels are available in all standard steel forms. They can be purchased heat treated or annealed to desired physical properties.

Most uses of nitriding steels are based on resistance to wear. An outstanding property is that these steels can be heated to as high as 538°C for long periods without softening.

The slick, hard surface produced also makes it ideal to prevent seizing, galling, and spalling, and it is not readily attacked by combustion products.

Nitrile Rubber

The nitriles are copolymers of butadiene and acrylonitrile, used primarily for applications requiring resistance to petroleum oils and gasoline. Resistance to aromatic hydrocarbons is better than that of neoprene but not as good as that of polysulfide. *Nitrile butyl rubber (NBR)* has excellent resistance to mineral and vegetable oils but relatively poor resistance to the swelling action of oxygenated solvents such as acetone, methyl ethyl ketone, and other ketones. It has good resistance to acids and bases except those having strong oxidizing effects. Resistance to heat aging is good, often a key advantage over natural rubber.

With higher acrylonitrile content, the solvent resistance of an NBR compound is increased but low-temperature flexibility is decreased. Low-temperature resistance is inferior to that of natural rubber, and although NBR can be compounded to give improved performance in this area, the gain is usually at the expense of oil and solvent resistance. As with SBR, this material does not crystallize on stretching, and reinforcing materials are required to obtain high strength. With compounding, nitrile rubbers can provide a good balance of low creep, good resilience, low permanent set, and good abrasion resistance.

Tear resistance is inferior to that of natural rubber, and electrical insulation is lower. NBR is used instead of natural rubber where increased resistance to petroleum oils, gasoline, or aromatic hydrocarbons is required. Uses of NBR include carburetor and fuel-pump diaphragms and aircraft hoses and gaskets. In many of these applications, the nitriles compete with polysulfides and neoprenes.

Essentially, the same techniques of emulsion polymerization employed in manufacture of general-purpose synthetic rubber may be used for production of nitrile polymers. Nitrile rubbers are supplied in various physical forms including sheet, crumb, powder, and liquid. The sheet is the most widely used type, with the other varieties offered for specialty applications.

Blends

An outstanding feature of nitrile rubber is its compatibility with many different types of resins permitting it to be easily blended with them. In combination with phenolic resins, it provides adhesives with especially high strengths. Other resins used include resorcinol formaldehyde, urea formaldehyde, alkyd, epoxy, and polyvinyl chloride (to produce Type 2 rigid PVC). Both slab- and crumb-type nitrile rubbers are used in this type of application, with the crumb type directly soluble and of special interest to adhesive manufacturers who do not have rubber-mixing equipment. Nitrile rubber-phenolic resin solvent solutions are used in shoe sole attaching adhesives, for structural bonding in aircraft, adhering automotive brake lining to brake shoes, and many other industrial applications.

The powder-type rubbers were also developed for blending with phenolic resins, primarily for the manufacture of improved impact phenolic molding powders.

The liquid nitrile polymer finds use as a tackifier and nonextractable plasticizer in molded rubber parts, cements, friction, and calendered stocks.

Both the liquid and powder are of interest as curing-type plasticizers and vinyl plastisols. Nitrile rubber-PVC blends of various types are used in many other fields including cable jacket, retractable cord, abrasion-resistant shoe soles, industrial face masks, boat bumpers, and fuel lines.

Composition

The ratio of butadiene to acrylonitrile in the commercially available rubbers ranges from a low of about 20% to as high as 50% acrylonitrile. The various grades are usually referred to as high, medium-high, medium-low, and low acrylonitrile content.

The high-acrylonitrile polymers are used in applications requiring maximum resistance to aromatic fuels, oils, and solvents. This would include oil well parts, fuel-cell liners, fuel hose, and other similar applications. The low acrylonitrile grade finds use in those areas requiring good flexibility at very low temperatures where oil resistance is of secondary importance. The medium types are most widely used and are satisfactory for all oil-resistant applications between these two extremes. Typical applications include conveyor belts, flexible couplings, soles, heels, floor mats, printing blankets, rubber rollers, sealing strips, aerosol bomb gaskets, milking inflations, seals, diaphragms, O-rings, packings, hose, washing machine parts, valves, and grinding wheels. These established uses give only a slight idea of products that are made of nitrile rubbers.

Physical properties of cured nitrile rubber parts are directly related to the ratio of butadiene and acrylonitrile in the polymer, as indicated in the following.

As acrylonitrile content increases

1. Oil and solvent resistance improves
2. Tensile strength increases
3. Hardness increases
4. Abrasion resistance improves
5. Gas impermeability improves
6. Heat resistance improves

As acrylonitrile content decreases

1. Low-temperature resistance improves
2. Resilience increases
3. Plasticizer compatibility increases

Properties

The polymer with the highest acrylonitrile content produces the highest tensile strength and hardness; it also exhibits the best resistance to fuels and oils. As the percentage of acrylonitrile decreases, there is a corresponding decrease in resistance to fuels and oils; at the same time, low-temperature flexibility characteristics are improved. Resiliency also increases. The lowest acrylonitrile polymer exhibits only moderate resistance to swelling in aromatic fluids but remains flexible at very low temperatures in the range of -57°C to -62°C .

Thus, properly compounded nitrile polymers will provide high tensile strength, excellent resistance to abrasion, low compression set, very good aging under severe operating conditions, and excellent resistance to a wide range of fuels, oils, and solvents. They are practically unaffected by alkaline solutions, saturated salt solutions, and aliphatic hydrocarbons, both saturated and unsaturated. They are affected little by fatty acids found in vegetable fats and oils or by aliphatic alcohols, glycols, or glycerols.

Nitrile rubbers are not recommended, generally, for use in the presence of strong oxidizing agents, ketones, acetates, and a few other chemicals.

Nitrocarburizing

Salt bath nitrocarburizing is a thermochemical process for improving the properties of ferrous metals. However, some tools and other high-alloy steels are susceptible to reductions in core hardness after standard nitrocarburizing. To prevent such losses, a low-temperature salt bath nitrocarburizing process has been developed with treatment temperatures as low as 480°C ; this process not only maintains core hardness but can also sometimes increase core hardness.

Processing

During salt bath nitrocarburizing, the part is immersed in a vessel of molten salt. Nitrogen and carbon in the salt react with the iron on the surface, forming a compound layer with an underlying diffusion zone. The compound layer consists of iron nitrides, chromium nitrides, or other such compounds, depending on the alloying elements in the steel, and small amounts of carbides.

Ranging in depth from 2.5 to 20 μm , the compound layer provides improvements in wear and corrosion resistance, as well as in service behavior and hot strength. Hardness of the compound layer, measured on a cross section, ranges from 700 HV on unalloyed steels up to 6000 HV on high chromium steels. Note that, this layer is formed from the base metal and is an integral part of it and is therefore not a coating. The diffusion zone can extend as deep as 1 mm, depending on the steel. This diffusion zone causes an increase in rotating-bending strength and rolling fatigue strength as well as pressure loadability.

Salt bath nitrocarburizing may be applied to a wide range of ferrous metals, from low-carbon to tool steels, cast iron to stainless steels. Specifically, the process

- Improves wear and corrosion resistance
- Reduces or eliminates galling and seizing
- Increases fatigue strength

- Raises surface hardness
- Provides highly predictable, repeatable results
- Performs consistently, even with varying contours and thicknesses within the same part or load
- Maintains dimensional integrity
- Shortens cycle times
- Offers flexibility and ease of operation

Conventional treatment temperatures are in the range of 580°C, but for highly alloyed steels as well as stainless steel and tool steels, this temperature can cause a reduction in core hardness. The aforementioned benefits, derived both from the nitrogen and carbon diffused into the metal surface, as well as the processing in a liquid bath, are often necessary for applications in which a reduction in core hardness is not acceptable. For this reason, a new low-temperature process was developed.

The low-temperature process normally takes place at 480°C, although it can operate at 480°C–520°C. This process has the following specific advantages:

- Core hardness and tensile strength are maintained in the tempered condition.
- Very thin compound layers can be formed.
- Distortion is extremely low.
- Formation of a compound layer on high-speed steels can be suppressed.
- Hardness of surface and diffusion layers can be customized.

This low-temperature process is beneficial for high-alloy steels such as stainless, tool, die, and high-speed steels. The steels include D2, D3, AISI 420, H11, H13, HNV3, 17-4PH, HSS36, and HSS M2.

Nitrocellulose

A compound made by treating cellulose with nitric acid, using sulfuric acid as a catalyst. Since cotton is almost pure cellulose, it was originally the raw material used, but alpha cellulose made from wood is now employed. The cellulose molecule will unite with from one to six molecules of nitric acid. *Trinitrocellulose* contains 9.13% nitrogen and is the product used for plastics, and lacquers, adhesives, and celluloid. It is classified as cellulose nitrate. The higher nitrates, or *pyrocellulose*, are employed for making explosives. *FNH powder*, or *flashless powder*, is nitrocellulose, which is nonhygroscopic and which contains a partially inert coolant, such as potassium sulfate, to reduce the muzzle flash of the gun. *Ballistite* is a rapid-burning, double-base powder used in shotgun shells and as a propellant in rockets. It is composed of 60% nitrocellulose and 40 nitroglycerin made into square flakes 0.005 in. (0.013 cm) thick or extruded in cruciform blocks.

Nitrogen

Nitrogen is an element (symbol N) that at ordinary temperatures is an odorless and colorless gas. The atmosphere contains 78% nitrogen in the free state. It is nonpoisonous and does not support combustion. Nitrogen is often called an inert gas and is used for some inert atmospheres for metal treating and in light bulbs to prevent arcing, but it is not chemically inert. It is a necessary element in animal and plant life, and as a constituent of many useful compounds. Lightning forms small amounts of nitric oxide from the air, which is converted into nitric acid and nitrates, and bacteria continuously convert atmospheric nitrogen into nitrates.

Nitrogen combines with many metals to form hard nitrides useful as wear-resistant metals. Small amounts of nitrogen in steels inhibit grain growth at high temperatures and also increase the strength of some steels. It is also used to produce a hard surface on steels.

Applications

Because of the importance of nitrogen compounds in agriculture and chemical industry, much of the industrial interest in elementary nitrogen has been in processes for converting elemental nitrogen into nitrogen compounds. The principal methods for doing this are the direct synthesis of ammonia from nitrogen and hydrogen, the electric arc process, which involves the direct combination of N₂ and O₂ to nitric oxide, and the cyanamide process.

Nitrogen Blanking

The use of nitrogen to produce an inert atmosphere.

Nitrogen Case Hardening

Nitriding. See *case hardening*.

Nitroglycerin

A heavy, oily liquid known chemically as *glyceryl trinitrate*. It is made by the action of mixed acid (90% nitric at 25–30 oleum) on very pure glycerol in the presence of sulfuric acid. It is highly explosive, detonating upon concussion. Liquid nitroglycerin when exploded forms carbonic acid, CO₂, water vapor, nitrogen, and oxygen; 1 lb (0.45 kg) is converted into 156.7 ft³ (4.4 m³) of gas. The temperature of explosion is about 628°F (330°C). For use as a commercial explosive, it is mixed with absorbents, usually kieselguhr or wood flour, under the name of *dynamite*. Cartridges of high density explode with greater shattering effect than those of low density. By varying the density and the mixture of the nitroglycerin with ammonium nitrate, which gives a heaving action, a great diversity in properties can be obtained. *Ethylene glycol dinitrate* (nitroglycol) and *diethylene glycol dinitrate* are also explosives. They are generally used to plasticize nitrocellulose.

Dynamites are rated on the percentage, by weight, of nitroglycerin that they contain. A 25% dynamite has 25% by weight of nitroglycerin. The regular grades range from 25% to 60%. *Ditching dynamite* has a 50% grade. *Extra dynamite* has half of the nitroglycerin replaced by ammonium nitrate. It is not so quick and shattering, and not as water-resistant, but is lower in cost. It is used for quarrying, stump and boulder blasting, and highway work.

Gelatin dynamite is made by dissolving a special grade of nitro cotton in nitroglycerin. It has less fumes, it is more water resistant, and its plasticity makes it more adaptable for loading solidly in holes for underground work. It is marketed as straight gelatin or as *ammonium gelatin*, called *gelatin extra*. The gelatin dynamites come in grades from 20% to 90%. *Blasting gelatin*, called *oil-well explosive*, is a 100% dense and waterproof gelatin with the appearance of crude rubber.

Dynamite is also sometimes used for explosive metal forming, as it releases energy at a constant rate regardless of confinement, and produces pressures up to 2×10^6 lb/in.² (1.379 MPa). For bonding *metal laminates*, a thin sheet, or film, of the explosive is placed on top of the composite, and the progressive burning of the explosive across the film produces an explosive force downward and in vectors

that produces a microscopic wave, or ripple, in the alloy bond that strengthens the bond but is not visible on a laminated sheet.

N Shell

The fourth layer of electrons surrounding the nucleus of an atom, having electrons with the principal quantum number 4.

NLGI Number

Abbreviation for the National Lubricating Grease Institute number, which is the numerical classification of the consistency of greases, based on the ASTM D 217 test.

NMR

See *nuclear magnetic resonance*.

No-Bake Binder

In foundry practice, a synthetic liquid resin sand binder that hardens completely at room temperature, generally not requiring baking; used in a *cold-setting process*.

Noble

(1) The positive direction of *electrode potential*, thus resembling noble metals such as gold and platinum. (2) In electrochemistry, the more cathodic of a pair of metals in the electrochemical series of relative potentials.

Noble Gases

The six inert gases, helium, neon, argon, krypton, xenon, and radon. More usually termed the rare gases.

Noble Metal

(1) A metal whose *potential* is highly positive relative to the hydrogen electrode. (2) A metal with marked resistance to chemical reaction, particularly to oxidation and to solution by inorganic acids. The term as often used is synonymous with *precious metal*. (3) Generally, metals that do not readily react with common environments, for example, gold, platinum, and palladium. Silver is usually also included.

Noble Potential

A *potential* more cathodic (positive) than the standard hydrogen potential.

Node

The connected portion of adjacent ribbons of honeycomb.

No-Draft (Draftless) Forging

A forging with extremely close tolerances and little or no *draft* that requires minimal machining to produce the final part. Mechanical properties can be enhanced by closer control of grain flow and by retention of surface material in the final component.

Nodular Cast Iron

Nodular cast irons, such as GGG 40, GGG 50, and GGG 60, have become popular for parts such as housings, wheel parts, crankshafts, and camshafts. These metals offer higher strength and toughness than other cast irons, a result of spherical inclusions of carbon in the metal matrix. Generally easy to machine, GGG 40 irons with higher ferrite content tend to produce built-up edges on the cutting tool. For materials such as GGG 60 and higher, abrasiveness increases as the pearlite content increases, which can result in rapid insert wear. These nodular iron grades present unique machining characteristics. See preferred term *ductile iron*.

Nodular Graphite

(1) Graphite in the nodular form as opposed to flake form (see *flake graphite*). Nodular graphite is characteristic of *malleable iron*. The graphite of nodular or *ductile iron* is spherulitic in form but called nodular. (2) One of the seven graphite shapes used to classify cast irons.

Nodular Pearlite

Pearlite that has grown as a colony with an approximately spherical morphology.

Nodular Powder

Irregularly shaped metal powder having knotted, rounded, or similar shapes.

Noise

Any undesired signal that tends to interfere with the normal reception or processing of a desired signal.

NOL Ring

A parallel filament- or tape-wound hoop test specimen developed by the Naval Ordnance Laboratory (NOL) (now the Naval Surface Weapons Laboratory) for measuring various mechanical strength properties of a material, such as tension and compression, by testing the entire ring or segments of it. Also known as parallel fiber-reinforced ring.

Nomarski Interference Technique

A microscopical technique utilizing polarized light to reveal slight topographical variations.

Nominal

This term is used vaguely in technical contexts to indicate concepts such as a token amount or a broad overall view.

Nominal Area of Contact

The area bounded by the periphery of the region in which macroscopic contact between two solid bodies is occurring. This is often taken to mean the area enclosed by the boundaries of a wear scar, even though the real area of contact, in which the solids are touching

instantaneously, is usually much smaller. See also *area of contact* and *apparent area of contact*.

Nominal Dimension

The size of the dimension to which the tolerance is applied. For example, if a dimension is 50 ± 0.5 mm (2.00 ± 0.02 in.), the 50 mm (2.00 in.) is the nominal dimension and the ± 0.5 mm (± 0.02 in.) is the tolerance.

Nominal Strength

See *ultimate strength*.

Nominal Stress

(1) The stress at a point calculated on the net cross section without taking into consideration the effect on stress of geometric discontinuities, such as holes, grooves, fillets, and so forth. The calculation is made using simple classic theory. (2) The stress is calculated on the basis of the external load acting on the minimum original dimensions of the component or test piece and ignoring matters such as stress raising effects at section changes or deformation under stress.

Nominal Value

A value assigned for the purpose of a convenient designation. A nominal value exists in name only. In dimensions, it is often an average number with a tolerance in order to fit together with adjacent parts.

Nonconformal Surfaces

(1) Surfaces whose centers of curvature are on the opposite sides of the interface, as in rolling element bearings or gear teeth. (2) In wear testing, a geometric configuration in which a “point” or “line” of contact is initially established between specimens before the test is started. Examples of nonconformal contacts are ball-on-ring and flat block-on-ring geometries.

Nonconforming

A quality control term describing a unit of product or service that does not meet normal acceptance criteria for the specific product or service. A nonconforming unit is not necessarily *defective*.

Noncontact Bearing

A bearing in which no solid contact occurs between relatively moving surfaces. Strictly speaking, a bearing in which *full-film lubrication* is occurring would be considered a noncontact bearing; however, this term is more typically applied to gas bearings and magnetic bearings. See also *gas lubrication* and *magnetic bearing*.

Noncorrosive Flux

A rosin-based soldering flux that, in neither its original nor residual form, chemically attacks the base metal.

Nondestructive Evaluation (NDE)

Broadly considered synonymous with nondestructive inspection (NDI). More specifically, the quantitative analysis of NDI findings to determine whether the material will be acceptable for its function, despite the presence of discontinuities. With NDE, a discontinuity can be classified by its size, shape, type, and location, allowing the investigator to determine whether or not the flaw(s) is acceptable. Damage-tolerant design approaches are based on the philosophy of ensuring safe operation in the presence of flaws.

Nondestructive Inspection

A process or procedure, such as ultrasonic or radiographic inspection, for determining the quality or characteristics of a material, part, or assembly, without permanently altering the subject or its properties. Used to find internal anomalies in a structure without degrading its properties or impairing its serviceability.

Nondestructive Testing/Examination

Any test or inspection system that provides information regarding the properties and characteristics of a component without causing unacceptable damage. These terms are most commonly used with respect to flaw detection systems, for example, dye penetrant and magnetic particle testing for surface defects and ultrasonic testing or radiography for internal defects. However, they may also include a wide range of techniques meeting the “no unacceptable damage” criterion including chemical spot tests or other analytical techniques, hardness measurement, and dimensional checks particularly when these are performed on-site.

Nonelectrolyte

A substance that does not ionize in solution. See *inter atomic bonding*.

Nonferrous

Metals and alloys not based on iron.

Nonfill

A forging condition that occurs when the die impression is not completely filled with metal. Also referred to as *underfill*.

Nonhygroscopic

Lacking the property of absorbing and retaining an appreciable quantity of moisture (water vapor) from the air.

Nonmagnetic

An imprecise term usually indicating that the material is not ferromagnetic. See *magnetic*.

Nonmagnetic Steels

These are steel and iron alloys used where magnetic effects cannot be tolerated. Manganese steel containing 14% manganese is nonmagnetic and casts readily but is not machinable. Nickel steels

and iron–nickel alloys containing high nickel content are nonmagnetic. Many mills regularly produce nonmagnetic steels containing from 20% to 30% nickel. Manganese–nickel steels and manganese–nickel–chromium steels are nonmagnetic and may be formulated to combine desirable features of the nickel and manganese steels. One nonmagnetic steel with a composition of 10.5%–12.5% manganese, 7%–8% nickel, and 0.25%–0.40% carbon has low magnetic permeability at low eddy current loss, can be machined readily, and work-hardens only slightly. The tensile strength is 551–2758 MPa, elongation 25%–50%, and specific gravity 8.02. It is austenitic and cannot be hardened. The 18–8 austenitic chromium–nickel steels are also nonmagnetic. A nonmagnetic alloy steel for watch gears and escapement wheels is not a steel but is a copper–nickel–manganese alloy containing 60% copper, 20% nickel, and 20% manganese. It is very hard but can be machined with diamond tools.

Nonmetallic Inclusions

See *inclusions*.

Non-Newtonian Viscosity

The apparent viscosity of a material in which the shear stresses are not proportional to the rate of *shear*.

Nonpropagating Cracks

Cracks that have ceased to grow. The term is most common in fatigue where a number of cracks initiate but only one continues to extend. However, many forms of cracks can become dormant because of some change in the stress field local to the crack tip or because of a change in the environment.

Nonresonant Forced and Vibration Technique

A technique for performing dynamic mechanical measurements in which a plastic sample is oscillated mechanically at a fixed frequency. Storage modulus and damping are calculated from the applied strain and the result of stress and shift in phase angle.

Nonrigid Plastic

For purposes of general classification, a plastic that has a modulus of elasticity either in flexure or in tension of not over 70 MPa (10 ksi) at 23°C (73°F) and 50% relative humidity.

Nonshattering Glass

Also referred to as *shatterproof glass*, *laminated glass*, or *safety glass*, and when used in armored cars, it is known as *bulletproof glass*. A material composed of two sheets of plate glass with a sheet of transparent resinoid between; the whole molded together under heat and pressure. When subjected to a severe blow, it will crack without shattering. The first of these was a German product marketed under the name of *Kinonglas*, which consisted of two clear glass plates with a cellulose nitrate sheet between, and it was first used for protective shields against chips from machines. Nonshattering glass is now largely used for automobile and car windows. The original cellulose nitrate interlining sheets had the disadvantage that they were not stable to light and became cloudy. Cellulose acetate was later substituted. It is opaque to actinic rays and prevents sunstroke but

has the disadvantage of opening in cold weather, permitting moisture to enter between the layers. The acrylic resins are notable for their stability in this use; in some cases, they are used alone without the plate glass, especially for aircraft windows. Polyvinyl acetal resins, as interlining for safety glass, are weather resistant and will not discolor. Polyvinyl butyral is much used as an interlayer, but an airplane glass at about 150°F (66°C) tends to bubble and ripple. Silicone resins used for this purpose withstand heat up to 350°F (177°C), and they are not brittle at subzero temperatures. Standard bulletproof glass is from 1.5 in. (3.81 cm), 3 ply, to 6 in., 5 or more ply.

Nonshielded Welding

Metal arc welding processes in which no shielding medium is applied to the weld zone to protect from contamination, etc.

Nonsoap Grease

A grease made with a thickener other than soap, such as clay or asbestos.

Nontransferred Arc

In plasma arc welding, cutting, and thermal spraying, an arc established between the electrode and the constricting nozzle. The workpiece is not in the electrical circuit. Compare with *transferred arc*.

Nonwetting

(1) The lack of metallurgical *wetting* between molten solder and a metallic surface due to the presence of a physical barrier on the metallic surface. (2) A condition in which a surface has contacted molten solder, but the solder has not adhered to all of the surfaces; base metal remains exposed.

Nonwoven Fabric

A planar textile structure for reinforced plastics produced by loosely compressing to gather fibers, yarns, rovings, and so forth, with or without a scrim cloth carrier. Accompanied by mechanical, chemical, thermal, or solvent means, or combinations thereof.

In the most general sense, nonwoven fabrics are fibrous-sheet materials consisting of fibers mechanically bonded together by interlocking or entanglement, by fusion, or by an adhesive. They are characterized by the absence of any patterned interlooping or interlacing of the yarns. In the textile trade, the terms *nonwovens* and *bonded fabrics* are applied to fabrics composed of a fibrous web held together by a bonding agent, as distinguished from felts, in which the fibers are interlocked mechanically without the use of a bonding agent. There are three major kinds of nonwovens based on the method of manufacture. Dry-laid nonwovens are produced by textile machines. The web of fibers is formed by mechanical or air-laying techniques, and bonding is accomplished by fusion bonding the fibers or by the use of adhesives or needle punching. Either natural or synthetic fibers, usually 2.5–7.6 cm in length, are used. Wet-laid nonwovens are made on modified papermaking equipment. Either synthetic fibers or combinations of synthetic fibers and wood pulp can be used. The fibers are often much shorter than those used in dry-laid fabrics, ranging from 0.64 to 1.27 cm in length. Bonding is usually accomplished by a fibrous binder or an adhesive. Wet-laid nonwovens can also be produced as composites, for example, tissue paper laminates bonded to a reinforcing

N

substrate of scrim. Spin-bonded nonwovens are produced by allowing the filaments emerging from the fiber-producing extruder to form into a random web, which is then usually thermally bonded. These nonwovens are limited commercially to thermoplastic synthetics such as nylons, polyesters, and polyolefins. They have exceptional strength because the filaments are continuous and bonded to each other without an auxiliary bonding agent. Fibers in nonwovens can be arranged in a great variety of configurations that are basically variations of three patterns: parallel or unidirectional, crossed, and random. The parallel pattern provides maximum strength in the direction of fiber alignment but relatively low strength in other directions. Cross-laid patterns (like wovens) have maximum strength in the direction of the fiber alignments and less strength in other directions. Random nonwovens have relatively uniform strength in all directions.

Normal

An imaginary line forming right angles with a surface or other lines sometimes called the perpendicular. It is used as a basis for determining angles of incidence reflection and refraction.

Normal Direction

That direction perpendicular to the plane of working in a worked material. See also *longitudinal direction* and *transverse direction*.

Normal Force

See *load*.

Normal Load

See *load*.

Normal Segregation

Segregation of the lower-melting-point constituents into the areas of a casting that solidify last. See *inverse segregation*.

Normal Solution

A solution having the equivalent weight in grams of the substance dissolved in 1 L of water.

Normal Stress

The stress component that is perpendicular to the plane on which the forces act. Normal stress may be either *tensile* or *compressive*.

Normal Temperature and Pressure

A reference environment conventionally, 0°C and 760 mm mercury.

Normal Wear

Loss of material within the design limits expected for the specific intended application. The concept of normal wear depends on economic factors, such as the expendability of a worn part.

Normality

A measure of the number of gram-equivalent weights of a compound per liter of solution. Compare with *molarity*.

Normalized Erosion Resistance

The volume loss rate of a specified reference material divided by the volume loss rate of a test material obtained under similar testing and analysis conditions. "Similar testing and analysis conditions" means that the volume loss rates of the two materials are determined at the corresponding portions of the erosion rate-time pattern, for example, the maximum erosion rate or the terminal erosion rate.

Normalizing

(1) Heating a ferrous alloy to a suitable temperature above the transformation range and then cooling in air to a temperature substantially below the transformation range. (2) The practice of heating to the austenitic range and cooling in air. This achieves recrystallization, eliminates residual stresses, and renders the steel relatively soft and ductile, although not quite as soft as the fully annealed condition. For steel capable of hardening upon air cooling, the term is inappropriate. See *steel*.

Normal-Phase Chromatography

This refers to liquid-solid chromatography or to bonded-phase chromatography with a polar stationary phase and a nonpolar mobile phase. See also *bonded-phase chromatography* and *liquid-solid chromatography*.

Nose Radius

The radius of the rounded portion of the cutting edge of a tool. See the term *single-point tool*.

Nosing

Closing in the end of a tubular shape to a desired curve contour.

Notch

See *stress concentration*.

Notch Acuity

Relates to the severity of the *stress concentration* produced by a given notch in a particular structure. If the depth of the notch is very small compared with the width (or diameter) of the narrowest cross section, acuity may be expressed as the ratio of the notch depth to the notch root radius. Otherwise, acuity is defined as the ratio of one-half the width (or diameter) of the narrowest cross section to the notch root radius. Same as *notch sharpness*.

Notch Brittle/Ductile, etc.

These terms refer to the notch sensitivity of a material, that is, its behavior and strength in the presence of a notch, which may be intentional, as in an impact test or inadvertent, as with a fatigue crack in service. The basic concept in determining notch sensitivity

is the difference in strength obtained from testing two bars of the material in question, one of which is plain and the other is notched. The strength of the notched bar is calculated on the remaining intact cross section beyond the notch. If the notched bar gives a higher strength, the material is termed notch ductile or notch strengthening; if lower, it is termed notch brittle or notch weakening. Alternatively, the two strengths may be identified in terms of the notch strength ratio whereby a value less than 100% is, conventionally, notch weak behavior. It should be noted, however, that the strength of the notched bar may be sensitive to notch geometry, particularly notch tip radius. The term notch ductile steel is sometimes used specifically for steels that meet some impact test specification.

Notch Constriction Ratio

A measure of the severity of a notch in terms of notch depth relative to section thickness. See also *notch sharpness*.

Notch Depth

The distance from the surface of a test specimen to the bottom of the notch. In a cylindrical test specimen, the percentage of the original cross-sectional area removed by machining an annular groove.

Notch Ductile

See *notch brittleness* or *notch brittle*.

Notch Ductility

The percentage reduction in area after complete separation of the metal in a tensile test of a *notched specimen*. The percentage reduction in cross-section area is calculated from the original cross-section area at the tip of the notch.

Notch Factor

Ratio of the resilience determined on a plain specimen to the resilience determined on a notched specimen.

Notch Rupture Ductility

Same as *notch ductility*.

Notch Rupture Strength

The ratio of applied load to original area of the minimum cross section in a *stress-rupture test* of a *notched specimen*.

Notch Sensitivity

The extent to which the sensitivity of a material to fracture is increased by the presence of a *stress concentration*, such as a notch, a sudden change in cross section, a crack, or a scratch. Low notch sensitivity is usually associated with ductile materials, and high notch sensitivity is usually associated with brittle materials. See *notch brittle*.

Notch Sharpness/Acuity

The sharpness at the tip of a notch or crack. It may be defined as a notch tip radius, some ratio between the radius and the specimen geometry, often specimen diameter: $2 \times$ notch tip radius. See *notch acuity* and *notch constriction ratio*.

Notch Specimen

A test specimen that has been deliberately cut or notched, usually in a V-shape, to induce and locate point of failure.

Notch Strength

The maximum load on a notched test specimen divided by the minimum cross-sectional area (the area at the root of the notch). Also called *notch tensile strength*. See *notch brittle*.

Notch Tensile Strength

See *notch strength*.

Notch Toughness

An imprecise term variously referring to the results of notched bar impact tests or to notch ductility or notch sensitivity. See *notch brittle*.

Notch Weak

See *notch brittle*.

Notched Bar Test

Any test in which the specimen has a notch positioned across the line of principal stress. In some contexts, the term is taken to refer specifically to bend test, but more generally, it includes impact, tensile, creep, bend and drop weight tests.

Notching Press

A mechanical press used for notching internal and external circumferences and also for notching along a straight line. These presses are equipped with automatic feeds because only one notch is made per stroke.

Novolac

A linear, thermoplastic, two-stage phenolic resin, which, in the presence of methylene or other cross-linking groups, reacts to form a thermoset phenolic. See also *phenolics*.

Nozzle (Metals)

(1) Pouring spout of a bottom-pour ladle. (2) On a hot-chamber die-casting machine, the thick-wall tube that carries the pressurized molten metal from the gooseneck to the die. (3) A device that directs shielding media in a welding or cutting torch. See also *bottom-pour ladle*, *hot chamber machine*, and *welding torch (arc)*.

N

Nozzle (Plastics)

The hollow-cored metal nose screwed into the injection end of either the heating cylinder of an injection machine or a transfer chamber when this is a separate structure. A nozzle is designed to form under pressure a seal between the heating cylinder or the transfer chamber and the mold. The shape of the front end of a nozzle may be either flat or spherical. See also *reciprocating screw injection molding*.

Nuclear

Referring to the nucleus of the atom.

Nuclear Cermet Fuel

A sintered fuel rod composed of a fissile carbide or oxide constituent and a metallic matrix.

Nuclear Charge

See *atomic number*.

Nuclear Cross Section (σ)

The probability that a nuclear reaction will occur between a nucleus and a particle, expressed in units of area (usually barns). See also *barn*.

Nuclear Magnetic Resonance

A phenomenon exhibited by a large number of atomic nuclei that is based on the existence of nuclear magnetic moments associated with quantized nuclear spins. These nuclear moments, when placed in a magnetic field, give rise to distinct nuclear Zeeman energy levels between which spectroscopic transitions can be induced by radio-frequency radiation. Plots of these transition frequencies, termed spectra, furnish important information about molecular structure and sample composition. See also *Zeeman effect*.

Nuclear Power

The controlled use of nuclear energy released by nuclear fission, that is, splitting of the atomic nucleus, or by chain reaction. In a nuclear reactor, the heat energy is used to produce steam to drive a turbine generator producing electrical power. Nuclear fusion occurs when elements with only a few neutrons per nucleus are treated to a very high temperature, which provides sufficient energy to initiate the fusion of the two simple nuclei to form an element with a larger nucleus. Again, the process is accompanied by the release of a large quantity of heat. In this fusion, hydrogen with only one neutron fuses to form helium with two. On earth, the process is the basis of the hydrogen bomb, but its development for civil use remains elusive.

Nuclear Structure

The atomic nucleus at the center of the atom, containing more than 99.975% of the total mass of the atom. Its average density is approximately 3×10^{11} kg/cm³, its diameter is approximately

10^{-12} cm, and thus is much smaller than the diameter of the atom, which is approximately 10^{-8} cm. The nucleus is composed of protons and neutrons. The number of protons is denoted by Z and the number of neutrons by N . The total number protons and neutrons in a nucleus is termed the mass number and is denoted by $A = N + Z$. See also *atomic structure*, *electrons*, *neutrons*, *protons*, *isobar*, *isotone*, and *isotope*.

Nucleate Boiling (of Water)

The production, at a heated surface, of steam as discrete bubbles rather than as a broad persistent film as occurs in steam blanketing.

Nucleating Agent (Plastics)

A foreign substance, often crystalline, usually added to a crystallizable polymer to increase its rate of solidification during processing.

Nucleation (Metals)

The initiation of a phase transformation at discrete sites, with the new phase growing on the nuclei. See also *nucleus* (2).

Nucleus

(1) The heavy central core of an atom, in which most of the mass and the total positive electric charge are concentrated. (2) The first structurally stable particle capable of initiating recrystallization of a phase or the growth of a new phase and possessing an interface with the parent metallic matrix. The term is also applied to a foreign particle that initiates such action.

Nuclide

A species of atom distinguished by the constitution of its nucleus. Nuclear constitution is specified by the number of protons, the number of neutrons, and energy content or by atomic number, mass number, and atomic mass. See also *isotope*.

Nugget

1. A small mass of metal, such as gold or silver, found free in nature.
2. The weld metal in a spot, seam, or projection weld.

Nugget Size

The diameter or width of the *nugget* obtained during resistance welding that is measured in the plane of the interface between the pieces joined.

Numerical Aperture

A measure of the ability of the objective lens of a microscope to gather light from a wide angle. It is a function of the angle of the cone of light that the lens will accept and the refractive index of the

medium between the lens and the specimen, usually air but sometimes oil. For a given magnifying power and focal length, the larger the numerical aperture, the better the resolution, that is, the fineness of detail that can be discerned.

Numerical Sphere

The measure of the light-collecting ability of an objective lens in a light microscope. It is defined as

$$NA = n \sin \alpha$$

where

n is the minimum refraction index of the medium (air or oil) between the specimen and the lens

α is the half-angle of the most oblique light rays that enter the front lens of the objective

n -Value

See strain-hardening exponent.

Nylon

The generic name, by common usage, for all synthetic polyamides.

Nylon Plastics

Although nylon polymers are most familiar in fiber form, their combination of excellent chemical and mechanical properties, plus their ability to be molded and extruded into precise forms, has permitted their use in a wide variety of nontextile applications. These range from hammerheads, gears, and rifle stocks to miniature coil forms and delicately colored personal products.

Characteristics

Nylons are a group of polyamide resins that are long-chain polymeric amides in which the amide groups form an integral part of the main polymer chain and that have the characteristic that when formed into a filament the structural elements are oriented in the direction of the axis. Nylon was originally developed as a textile fiber, and high tensile strengths, above 344 MPa, are obtainable in the fibers and films. But this high strength is not obtained in the molded or extruded resins because of the lack of oriented stretching. When nylon powder that has not precipitated from solution is pressed and sintered, the parts have high crystallinity and very high compressive strength, but they are not as tough as molded nylon.

Production

Nylons are produced from the polymerization of a dibasic acid and a diamine. The most common one of the group is that obtained by the reaction of adipic acid with hexamethylenediamine.

More specifically, nylons may be made by the amidation of diamines with dibasic acids, for example, hexamethylenediamine plus adipic acid (Type 6/6 nylon) or hexamethylenediamine and sebacic acid (Type 6/10 nylon). They can also be made by the

polymerization of amino acids or their derivatives, for example, polycaprolactam (Type 6 nylon) and polymerized 11-aminoun-decanoic acid (Type 11 nylon).

Types

Nylon 6/6 is the most widely used of the nylon plastics because of its overall balance of properties. The second most widely used of the nylon family is nylon 6. Type 6/6 nylon resins have higher heat resistance, abrasion resistance, stiffness, and hardness than type 6 nylons. The type 6 nylon resins are tougher and more flexible than type 6/6 nylons, and they have a wider processing window.

Nylon 6/12 absorbs less moisture and, therefore, maintains most mechanical and electrical properties better in high-humidity environments. But the reduced moisture sensitivity is accompanied by the lower strength, low or stiffness, lower use temperatures, and higher costs.

Nylons 11 and 12 have lower moisture absorption combined with superior resistance to fuels, hydraulic oils, and most automotive fluids. The melting point of nylons 11 and 12 (180°C–185°C) is the lowest of the commercial polyamides. These two polyamides are often combined with plasticizers to generate a flexible, tough material suitable for tubing extrusion. Recently, nylon 12/12 was introduced with a slightly higher use temperature while maintaining good fuel resistance. Nylon 6/6T resins have low moisture absorption, and they are much stronger, stiffer, tougher, fatigue resistant, and more heat resistant than type 6/6 nylons. The Ultramid type 6/6 T resins also have the better resistance to hot oils and fats than type 6/6 nylons. Reinforced grades of type 6/6T nylon resins also are available.

Nylon 4/6 is the latest version of the short-repeat-unit polyamides. Its melting point of 295°C is 12.2°C above that for nylon 6/6 and is the highest in the polyamide family. The inherent molecular symmetry of nylons 4/6 results in self-nucleation, rapid crystal growth, and, thus, a higher level of crystallinity. This higher level of crystallinity leads to faster setup and, hence, faster injection-molding cycles, up to 30% faster than for 6/6. Nylon 4/6 absorbs more water than nylon; however, its dimensional stability is similar to nylon 6/6 due to its high crystallinity.

Higher crystallinity has a major effect on nearly all properties leading to higher strength, higher stiffness, high HDT, high fatigue resistance, high wear resistance, and high creep resistance. Semicrystalline polymers maintain useful properties above the glass transition in contrast to amorphous polymers, which transformed into a viscous mass. Nylon 4/6, with its unusually high crystallinity, maintains a higher level of performance at elevated temperatures. The HDT for reinforced nylon 4/6 is 545°C.

Nylon resin is available in a wide range of reinforcement levels, filler types, toughening agents, stabilizers, and flame-retardant additives. Newer flame retardants can provide good flammability ratings (UL 94V-0) while maintaining acceptable electrical properties.

Toughening technology has reduced sensitivity providing notched Izod values over 15 ft lb/in.

Properties

Property comparisons among commercial grades of nylon vary widely because so many formulations are available. In general, however, nylons of excellence fatigue resistance, low coefficient of friction, good toughness (depending on degree of crystallinity), and they resist a wide spectrum of fuels, oils, and chemicals. They are

inert to biological attack and have adequate electrical properties for most voltages and frequencies.

The crystalline structure of nylons, which can be controlled to some degree in processing, affects stiffness, strength, and heat resistance. Low crystallinity imparts greater toughness, elongation, and impact resistance but at the sacrifice of tensile strength and stiffness.

Nylon 6/6, 6/6T, and 4/6 have the lowest permeability of nylons by gasoline, mineral oil, and fluorocarbon refrigerants. Nylons 6/12 and 6/6T are used where lower moisture absorption (and better dimensional stability) is needed.

All nylons absorb moisture from the environment; however, type 6/6T nylon has much lower moisture absorption than any other type of nylon resin. Moisture absorption leads to dimensional and property changes dependent upon the equilibrium level absorbed. At elevated temperatures, the moisture equilibrium level decreases above 88°C, nylons begin to dry out by a combination of internal diffusion and surface volatile emission. Extended exposure to temperatures above 121°C will reduce moisture content to about 0.1% (similar to dry-as-molded content).

Nylons are sensitive to ultraviolet radiation. Weatherability will be reduced unless ultraviolet stabilizers are incorporated into the formulation. Carbon black is the most commonly used ultraviolet stabilizer. Carbon black lowers the ductility and toughness as trade-off for ultraviolet stability.

Nylons have good resistance to creep and cold flow compared with many less rigid thermoplastics. Creep resistance is better at higher levels of crystallinity as demonstrated in nylon 4/6. Creep can be calculated from long-term apparent modulus under load data.

Processing

Nylons are generally fabricated by injection molding or by extrusion. Precise, intricate shapes of a variety of colors can be molded with little or no finishing required. These can often replace an assembly of several metal parts. Thus, even where nylons cost more on a per-volume basis than the common die-casting metals, economies in finishing and assembly often result in lower ultimate costs.

Tubing and rod stock manufacture, plus the coating of wire and cable, are the major forms of nylon extrusion. Film and relatively complex cross sections are also made but in less volume. In general, tubing, film, and other unsupported shapes require higher melt viscosity than is desirable for injection molding. Most manufacturers of nylon supply these high-viscosity grades.

Applications

Nylons are usually specified because of their combination of properties. Gears, bearings, cams, clutch facings, and similar mechanical parts require their strength, stiffness, low coefficient of friction, and resistance to fatigue and abrasion. In cases where oiling or greasing is apt to be neglected, as in home appliances, or is undesirable from a contamination standpoint, as in textile and food-handling machinery, nylon parts usually perform satisfactorily without any lubrication whatsoever.

Designers often utilize the mechanical properties of nylons, plus one or more characteristics of particular value. For example, the nylon housing for an electric drill must be tough, stiff, dimensionally stable, and resistant to commonly encountered lubricants and

solvents. However, its electrical nonconductivity and safety are the critical advantages.

Similarly, one manufacturer makes an entire rifle stock, plus many of the moving parts of the rifle, out of nylon. It is far lighter and tougher than wood and provides moving surfaces that do not need lubrication. The ability of nylon to be molded into precise sections thus permits custom-quality guns to be mass-produced.

By utilizing different properties, marine electrical stuffing tubes of nylon capitalize on the durability, lightness, resistance to corrosion, and cost advantage of the resin over machined brass. Washing machine mixing valves and valves for the dispensing of hot beverages require the mechanical properties of nylon and its excellent resistance to the effects of hot water.

The coating of wire and cable construction is the most important extrusion application of nylon. Although it is most commonly used as a jacket over a primary insulator such as polyvinyl chloride or polyethylene to impart resistance to lubricants, abrasion, and to the effects of high temperature, its electrical properties are adequate for low-voltage uses.

Exercise bikes used in health clubs undergo about 10 h of use per day. Further, to be competitive in today's hot exercise-equipment marketplace, one must design bikes to last from 5 to 7 years. The jump on the competition is a newly designed thermoplastic composite pillow block, the structure that supports the driveshaft of the bike. The material selected was a long-glass-fiber-reinforced nylon 6/6 structural composite. When compared to conventional short-fiber-reinforced thermoplastics, then nylon 6/6 structural composites have enhanced mechanical properties, while remaining lightweight. As an added bonus, this combination of properties reduces the weight of the pillow block from 3.68 to 0.69 g.

A nylon foot brace for kayakers has become the standard of excellence. The brace consists of a rail screwed into the bottom of the boat, and a footpad that slides up and down the rail to fit the kayaker's leg. Today, most kayak makers feature the brace as standard equipment. It consists of glass-reinforced, nylon 6, injection-molded resins.

The nylon combines high-strength, stiffness, and heat-deflection characteristics while extending the retention of these properties at high temperatures and a lower cost than competitive materials.

A new sports car features a lightweight, high-performance nylon air-intake manifold with a molded-in fuel rail. The automaker claims the integrated air-fuel module with two fuel passages into the body of the intake manifold breaks the mold when it comes to under-the-hood components. It uses a nylon manifold/fuel rail using these fusible-core, injection-molding techniques. The manifold, with its molded-in fuel rail, weighs about 3.68 g. That is nearly 50% less than a similar design based on pressure cast aluminum would weigh. The smooth inner walls of the injection-molded manifold increase airflow. This, combined with the low thermal conductivity of the nylon manifold, helps improve engine performance up to 5% more than that of an aluminum counterpart. And the nylon manifold insulates the air inside from engine heat, allowing high-density air to flow into the engine. The specially formulated 6/6 nylon resists hot engine temperatures and attacks from oil, gasoline, and battery vapors. It also produces a manifold that better withstands engine vibration stresses while reducing engine noise.

As a wire insulation, nylon is valued for its toughness and solvent resistance. Nylon fibers are strong, tough, and elastic and have a high gloss. The finer fibers are easily spun into yarns for weaving or knitting either alone or in blends with other fibers, and they can be

crimped and heat-set. For making carpets, nylon staple fiber, lofted or wrinkled, is used to give the carpet a bulky texture resembling wool. Tire cord, made from nylon 6 of high molecular weight, has the yarn drawn to four or five times its original length to orient the polymer and give one half twist per inch. Nylon film was made in thicknesses down to 0.005 cm for heat-sealed wrapping, especially for food products where tight impermeable enclosures are needed.

Nylon sheet, for gaskets and laminated facings, comes transparent or in colors in thicknesses from 0.013 to 0.152 cm. Nylon monofilament is used for brushes, surgical sutures, tennis strings, and fishing lines. Filament and fiber, when stretched, have a low specific gravity down to 1.068, and the tensile strength may be well above 344 MPa. Nylon fibers made by condensation with oxalic acid esters have high resistance to fatigue when wet.

Taylor & Francis

Taylor & Francis Group

<http://taylorandfrancis.com>

Objective

The primary magnifying system of a microscope. A system, generally of lenses, less frequently of mirrors, forming a real, inverted, and magnified image of the object.

Objective Aperture

See aperture (*electron*); an aperture (*optical*).

Objective Lens

The lens in a microscope closest to the specimen being examined. It forms the initial magnified image that in turn is further magnified by the eyepiece or ocular lens. The objective lens, therefore, controls the resolution that can be achieved. See *microscope* and *numerical aperture*.

Oblique Evaporation Shadowing

The condensation of evaporated material onto a substrate that is inclined to the direct line of the vapor stream to produce shadows. See also *shadowing*.

Oblique Illumination

Illumination from light inclined at an oblique angle to the optical axis.

Observed Value

The particular value of a characteristic determined as a result of a test or measurement.

Obsidian

A jet-black volcanic natural glass formed by rapid cooling of viscous lava. Although its composition varies, it is highly siliceous.

Occluded

Closed or shut off or, in a chemical context, absorbed.

Ochre

A compact form of earth used for paint pigments and as a filler for linoleum, also spelled *ocher*. It is an argillaceous and siliceous material, often containing compounds of barium or calcium, and owing the yellow, brown, or red colors to hydrated iron oxide. The tints depend chiefly upon the proportions of silica, white clay, and iron oxide. Ochres are very stable as pigments. They are prepared by careful selection, washing, and grinding in oil. They are

inert and are not affected by light, air, or ordinary gases. They are rarely adulterated, because of their cheapness, but are sometimes mixed with other minerals to alter the colors. *Chinese yellow* and many other names are applied to the ochres. *Golden ochre* is ochre mixed with chrome yellow. *White ochre* is an ordinary clay. *Sienna* is a brownish-yellow ochre found in Italy and Cyprus. The material in its natural state is called *raw sienna*. *Burnt sienna* is a material calcined to a chestnut color. Indian red and Venetian red are hematite ochres.

Octahedral

Eight sided. The octahedral planes of a cubic structure are those having Miller indices of (111).

Octahedral Plane

In cubic crystals, a plane with equal intercepts on all three axes.

Ocular

See *eyepiece*.

Ocular Lens

The lens in a microscope closest to the eye. It magnifies the image initially produced by the objective lens. See *microscope*.

Ocvirk Number

A dimensionless number used to evaluate the performance of journal bearings and defined by the following equation:

$$\text{Ocvirk number} = \frac{P}{\eta U} \left\{ \frac{c}{r} \right\}^2 \left\{ \frac{d}{b} \right\}^2$$

where

P is the load per unit width
 η is the dynamic viscosity
 U is the surface velocity
 c is the radial clearance
 r is the bearing surface
 b is the bearing length
 d is the bearing diameter

This number may be used in its inverted form and is related to the *Sommerfeld number*.

O.D.

Outside diameter.

O

Off Time

In resistance welding, the time that the electrodes are off the work. This term is generally applied where the welding cycle is repetitive.

Offal

The material trimmed from blanks or formed panels.

Offhand Grinding

Grinding where the operator manually forces the wheel against the work, or vice versa. It often implies casual manipulation of either grinder or work to achieve the desired result. Dimensions and tolerances frequently are not specified or are only loosely specified; the operator relies mainly on visual inspection to determine how much grinding should be done. Contrast with *precision grinding*.

Offset (Yield/Stress/Strength)

(1) Same as proof stress. (2) The distance along the strain coordinate between the initial portion of a stress–strain curve and a parallel line that intersects the stress–strain curve at a value of stress (commonly 0.2%) that is used as a measure of the *yield strength*. Used for materials that have no obvious *yield point*. See *tensile test* and *stress–strain curve*.

Offset Yield Strength

The stress at which the strain exceeds by a specific amount (the *offset*); an extension of the initial, approximately linear, proportional portion of the stress–strain curve. It is expressed in force per unit area.

Ohm (Ω)

The SI unit of electrical resistance equal to the resistance through which a current of 1 amp will flow when there is a potential difference of 1 V across it.

Ohm's Law

In a conductor, volts = amps $\times$ ohms, where the voltages are the potential drop across the conductor, amps is the current flowing in it, and ohms is its resistance. It is applicable to direct current circuits but not usually to alternating current circuits.

Oil

A liquid of vegetable, animal, mineral, or synthetic origin that feels slippery to the touch.

Oil Canning

See *canning*.

Oil Content

The amount of oil that an impregnated part, such as a self-lubricating bearing, retains.

Oil Cup

A device connected to a bearing that uses a wick, valve, or other means to provide a regulated flow of a lubricant.

Oil Flow Rate

The rate at which a specified oil will pass through a porous sintered powder compact under specified test conditions.

Oil Fog Lubrication

See *mist lubrication*.

Oil Groove

A channel or channels cut in a bearing to improve oil flow through the bearing. A similar groove may be used for grease-filled bearings.

Oil Hardening

The process of hardening steels by quenching into oil. See *steel*.

Oil Hardening Steel

Steel containing a sufficient quantity of alloying elements to cause it to fully harden when quenched into oil. Unless specified to the contrary, it is usually implicit that full hardening should be achieved in a round bar of 50 mm (2 in.) diameter. See *steel* and *hardenability*.

Oil Impregnation

The filling of a sintered skeleton body with oil by capillary attraction or under influence of an external pressure or a vacuum.

Oil Less Bearing

(1) A bearing manufactured by sintering metal powders with a proportion of graphite as a lubricant. (2) Sintered metal, produced so as to leave a considerable volume of voids, and subsequently impregnated prior to installation with a lubricant that may be a grease or even thick oil. This usage is a bit dubious as it indicates not an absence of oil but only that the bearing does not need further oil addition in service. See also *oilite bearing* and preferred term *self-lubricating bearing*.

Oil Permeability

A measure of the capacity of a sintered powder metallurgy bearing to allow the flow of an oil through its open pore system.

Oil Pocket

A depression designed to retain oil on a sliding surface.

Oil Quenching

Hardening of carbon steel in an oil bath. Oils are categorized as conventional, fast, and martempering.

Oil Ring Lubrication

A system of lubrication for horizontal shafts. A ring of larger diameter rotates with the shaft and collects oils from a container beneath.

Oil Starvation

A condition in which a bearing, or other *tribocomponent*, receives an inadequate supply of lubricant.

Oil Wedge

When at rest, the shaft journal carried in a plain bearing may penetrate the oil film and contact the bearing material. However, assuming a satisfactory design and adequate lubricant supply, a rotating shaft induces hydrodynamic forces in the lubricant that develop a standing wedge of oil slightly offset from the bottom centerline. The shaft and rise on this wedge. The bore of the bearing may contain a circumferential recess of complex form over much of its length to develop and stabilize the wedge.

Oil Whirl

Instability of a rotating shaft associated with instability in the lubricant film. Oil whirl should be distinguished from shaft whirl, which depends only on the stiffness of the shaft.

Oilcloth

A fabric of woven cotton, jute, or hemp, heavily coated with turpentine and resin compositions, usually ornamented with printed patterns, and varnished. It was employed chiefly as a floor covering but a light, flexible variety having a foundation of muslin is used as a covering material. This class comes in plain colors or in printed designs. It was formally the standard military material for coverings and ground protection but has been replaced by synthetic fabrics. *Oilskin* is a cotton or linen fabric impregnated with linseed oil to make it waterproof. It was used for coverings for cargo and for waterproof coats but has now been replaced by coated fabrics. *Oiled silk* is a thin silk fabric impregnated with blown linseed oil that is oxidized and polymerized by heat. It is waterproof, very pliable, and semitransparent. It was much used for linings but has now been replaced by fabrics coated with synthetics.

Oiliness

See *lubricity*.

Oilite Bearing

A sintered powder metal bearing containing a considerable volume of voids, typically 30%. It may be impregnated with oil prior to installation or may be fed in service, the void contents providing a reservoir during oil flow interruption.

Oils

A large group of fatty substances that are divided into three general classes: vegetable oils, animal oils, and mineral oils. The *vegetable oils* are either fixed or volatile oils. The fixed oils are present in the plant in combined form and are largely glycerides of stearic, oleic, palmitic, and other acids, and they vary in consistency from

light fluidity to solid fats. They nearly all boil at 500°F–600°F (260°C–316°C), decomposing into other compounds. The volatile, or essential, oils are present in uncombined form and bear distillation without chemical change.

Seed oils, or *oilseeds*, obtained from various plant seeds, are fatty acids of varying chain lengths containing hydroxy, keto, epoxy, and other functional groups. The oils are chemically very pure. Among important uses of these oils are for polymers, surface coatings, plasticizers, surfactants, and lubricants. The seeds of the *Chinese tallow tree* are coated with a semisolid fat. An oil similar to linseed oil is inside the kernel. The oil can be used as a substitute for cocoa butter and for fatty acids in cosmetics.

Fish oils are thick, with a strong odor. Vegetable and animal oils are obtained by pressing, extraction, or distillation. Oils that absorb oxygen easily and become thick are known as *drying oils* and are valued for varnishes, because on drying they form a hard, elastic, waterproof film. Unsaturation is proportional to the number of double bonds, and in food oils, these govern the cholesterol depressant effect of the oil. Oils and fats are distinguished by consistency only, but waxes are not oils. *Mineral oils* are derived from petroleum or shale and are classified separately. The most prolific sources of vegetable oils are palm kernels and copra.

Under comparable aggressive plantation work, 10–20 times more palm and coconut oil can be produced per acre than peanut or soybean oil. Babassu oil is almost chemically identical with coconut oil, and vast quantities of babassu nuts grow wild in northeast Brazil.

Blown oils are fatty oils that have been oxidized by blowing air through them while hot, thereby thickening the oil. They are mixed with mineral oils to form special heavy lubricating oils, such as marine engine oil, or are employed in cutting oils. They are also used in paints and varnishes, as the drying power is increased by the oxidation, the flashpoint and the iodine value are both lowered by the blowing. The oils usually blown are rapeseed, cottonseed, linseed, fish, and whale oils.

Oilstone

A fine-grained, slaty silica rock for sharpening edged tools. The bluish-white and opaque white oilstones, fine grains from Arkansas, are called *novaculite*, and they received their name because they were originally used for razor sharpening. They are composed of 99.5% chalcedony silica and are very hard and fine grain. Novaculite is a deposit from hot springs. It is fine grained, and the ordinary grades are employed for the production of silica refractories. Arkansas oilstones are either hard or soft and have a waxy luster. They are shipped in large slabs or blocks or in chips for tumbling barrel finishing. *Artificial oilstones* are also produced of aluminum oxide. *India oilstone* was originally blocks of emery, but the name now may refer to aluminum oxide stones.

Olefin

A group of unsaturated hydrocarbons of the general formula C_nH_{2n} and named after the corresponding paraffins by the addition of -ene or sometimes -ylene to the root.

Olefin Copolymers

The principal olefin copolymers are the polyallomers, ionomers, and ethylene copolymers. The polyallomers, which are highly crystalline, can be formulated to provide high stiffness and medium impact strength, moderately high stiffness and high impact strength, high

O

impact strength, or extrahigh impact strength. Polyallomers, with their unusually high resistance to flexing fatigue, have “hinge” properties better than those of polypropylenes. They have the characteristic milky color of polyolefins, are softer than polypropylene, but have greater abrasion resistance. Commonly injection molded, extruded, and thermoformed, polyallomers are used for such items as typewriter cases, snap clasps, threaded container closures, embossed luggage shells, and food containers.

Ionomers are nonrigid plastics characterized by low density, transparency, and toughness. Unlike polyethylenes, density and properties are not crystalline dependent. Their flexibility, resilience, and high molecular weight combine to provide high abrasion resistance. They have outstanding low-temperature flexural properties but upper temperature use is limited to 71°C. Resistance to attack from organic solvents and stress cracking chemicals is high. Ionomers have high melt strength for thermoforming and extrusion coating and a broad temperature range for blow molding and injection molding. Representative ionomer parts include injection-molded containers, housewares, tool handles, and closures; extruded film, sheet, electrical insulation, and tubing; and low-molded containers and packaging.

There are four commercial ethylene copolymers, of which ethylene vinyl acetate (EVA) and ethylene ethyl acrylate (EEA) are the most common; EVA copolymers approach elastomers and flexibility and softness, although they are processed like other thermoplastics. Many of their properties are density dependent, but in a different way from that of polyethylenes. Softening temperature and modulus of elasticity decrease as density increases, which is contrary to the behavior of polyethylene. Similarly, the transparency of EVA increases with density to a maximum that is higher than that of polyethylenes, which become opaque when density increases above around 0.935 g/cc. Although the electrical properties of EVA are not as good as those of low-density polyethylene, they are competitive with vinyl and elastomers normally used for electrical products. The major limitation of EVA plastics is the relatively low resistance to heat and solvents; the Vicat softening point is 64°C. EVA copolymers can be injection, blow, compression, transfer, and rotationally molded; they can also be extruded. Molded parts include appliance bumpers in a variety of seals, gaskets, and bushings. Extruded tubing is used in beverage vending machines and for hoses for air-operated tools and paint spray equipment.

EEA is similar to EVA in its density–property relationships. It is also generally similar to EVA in high-temperature resistance, and like EVA, it is not resistant to aliphatic and aromatic hydrocarbons or their chlorinated versions. However, EEA is superior to EVA in environmental stress cracking and resistance to ultraviolet radiation. Similar to EVA, most of the applications of EEA are related to the outstanding flexibility and toughness of the plastic. Typical uses are household products such as trash cans, dishwasher trays, flexible hose and water pipe, and film packaging.

Two other ethylene copolymers are ethylene hexane (EH) and ethylene butane (EB). Compared with the other two, these copolymers have greater high-temperature resistance; their useful service range is between 66°C and 88°C. They are also stronger and stiffer and, therefore, less flexible than EVA and EEA. In general, EH and EB are more resistant to chemicals and solvents than the other two, but their resistance to environmental stress cracking is not as good.

Oleic Acid

Also called *red oil*, *elaine oil*, *octadecenoic acid*, and *rapic acid*, although the latter is a misnomer based on a former belief that it was the same as the erucic acid of rapeseed. It occurs in most

natural fats and oils in the form of glyceride, and it is obtained in the process of saponification or by distillation. Much of this acid is obtained from lard and other animal fats, but *Emery 3758-R* is produced from soybean or other vegetable sources by hydrolysis of *glycerol trioleate*. It is an oily liquid with a specific gravity of 0.890, and below 57°F (14°C), it forms colorless needles if heated to the boiling point of water, and it reacts with oxygen to form a complex mixture of assets, including a small percentage of acetic and formic acids. When reacted with potassium hydroxide, it is converted to an acetate and a palmitate. It is also readily converted to pelargonic and other acids for making plastics. Oleic acid is a basic foodstuff in the form of the glyceride, and the acid has a wide use for making soaps, as a chemical raw material, and for finishing textiles. In soluble oils and cutting compounds, it forms sodium oleate. The two commercial grades of oleic acid, yellow and red, are known as *distilled red oil* and *saponified*. Aluminum oleate is used for thickening lubricating oils.

Oligomer

A polymer consisting of only a few monomer units, for example, a dimer, trimer, and tetramer, or their mixtures.

Oliver

A blacksmith's forge with two or more dies, the lower halves of which were set on a single anvil, the upper halves being foot actuated by individual treadles.

Olivine

A translucent mineral, usually occurring in granular form, employed as a refractory. The formula is usually given as $(\text{Mg} \cdot \text{Fe})_2 \cdot \text{SiO}_4$, but it is a solid solution of *forsterite*, $2\text{MgO} \cdot \text{SiO}_2$, and *fayalite*, $2\text{FeO} \cdot \text{SiO}_2$. The fayalite lowers the refractory quality, but forsterite is not found alone. The mineral is also called *chrysolite*, and the choice green stones used as gems are called *peridot*. The melting point of forsterite is 3470°F (1912°C). When it is mixed with chrome ore, the low-fusing elements form a black glass that presents a nonporous face. Some refractory material marketed as forsterite may be olivine blended with magnesite or may be serpentine treated with magnesite. *Forsterite firebrick* in the back walls of basic open-hearth steel furnaces gives longer life than silica brick but only two-thirds that of chrome–magnesite brick. Forsterite refractories are usually made from olivine rock to which MgO is added to adjust the composition to $2\text{MgO} \cdot \text{SiO}_2$. *Olivine sand* is substituted for silica sand as a foundry sand, where silica is expensive. When olivine is used as a foundry sand, it is noted that the heat-resisting qualities decrease with particle size. Olivine contains 27%–30% magnesium metal and is also used to produce magnesium by the electrolysis of the chloride. *Magnesium phosphate* fertilizer is made by fusing olivine with phosphate rock at 2912°F (1600°C), tapping off the iron, and spray cooling and crushing the residue. It contains 20% citric-acid-soluble phosphate and is useful for acid soils.

Olsen Ductility Test

A *cupping test* in which a piece of sheet metal, restrained except at the center, is deformed by a standard steel ball until fracture occurs. The height of the cup at the time of fracture is a measure of the ductility. Similar to the *Erichsen test*.

Omega Phase

A nonequilibrium, submicroscopic phase that forms in titanium alloys as a nucleation growth product; often thought to be a transition phase during the formation of α from β . It occurs in metastable β alloys and can lead to severe embrittlement. It typically occurs during aging at low temperature but can also be induced by high hydrostatic pressures.

One-Component Adhesive

Adhesive material incorporating a latent hardener or catalyst that is activated by heat.

One-Shot Molding

In the urethane foam field, a system in which the isocyanate, polyol, catalyst, and other additives are mixed together directly, and a foam is produced immediately. Compare with *prepolymer molding*.

Onyx

A variety of chalcedony silica mineral differing from agate only in the straightness of the layers. The alternate bands of color are usually white and black or white and red. Onyx is artificially colored in the same way as agate. It is used as an ornamental building stone, usually cut into slabs, and used as decorative articles. *Onyx marble* is limestone with impurities arranged and banded in layers. *Opalized wood* is an onyx-like petrified wood from Idaho. It is cut into ornaments.

Opacifiers

Materials used in ceramic glazes and vitreous enamels primarily to make them nontransparent, but opacifiers may also enhance the luster, control the texture, promote craze resistance, or stabilize the color of the glaze. An opacifier must have fire resistance so as not to vitrify or decrease the luster. Tin oxide is a widely used white opacifier, and up to 3% also increases the fusibility of the glaze or enamel. Titanium oxide adds scratch hardness and high acid resistance to the enamel. It also increases the flow, making possible thinner coats that minimize chipping. Opacifiers may also serve as the pigment colors. Thus, cobalt oxide gives a blue collar, and platinum oxide gives a gray collar. Lead chromate gives an attractive red color on glazes fired at 1652°F (900°C), but when fired at 1832°F (1000°C), the lead chromate decomposes and a green chromium oxide is formed. If the glaze is acid, the basic lead chromate is altered and the color tends toward green. The *zirconium opacifiers* have a wide range of use from ordinary dishes to high-heat electrical porcelain and sanitary-ware enamels. The amount of zirconium oxide used is a minimum of 3%. Lead oxide is used to lower the melting point of a glaze. Matte effects are obtained by adding barium oxide, magnesium, or other materials to the opacifier.

Open Arc Welding

Welding operations during which the electric arc is visible.

Open Assembly Time

The time interval between the spreading of the adhesive on the adherend and the completion of the assembly of the parts for bonding.

Open Dies

Dies with flat surfaces that are used for preforming stock or producing and forgings.

Open (Gap) Joint

A joint to be welded in which the components have a significant gap deliberately set between them prior to welding. Filler metal is deposited in the gap.

Open Pore

A pore open to the surface of a powder compact. See also *intercommunicating porosity*.

Open Porosity

See *interconnected porosity*.

Open Rod Press

A *hydraulic press* in which the slide is guided by vertical, cylindrical rods (usually four) that also serve to hold the crown and bed in position.

Open-Back Inclined Press

A vertical crank press that can be inclined so that the bed will have an inclination generally varying from 0° to 30°. The formed parts slide off through an opening in the back. It is often called an OBI press.

Open-Cell Cellular Plastic

Foamed or cellular plastic with cells that are generally interconnected.

Open-Cell Foam

Foamed or cellular polymeric material with cells that are generally interconnected. Closed cell refers to cells that are not interconnected.

Open-Circuit Potential

The *potential* of an electrode measured with respect to a reference electrode or another electrode when no current flows to or from it.

Open-Circuit Voltage

The voltage between the output terminals of a welding machine when no current is flowing in the welding current.

Open-Die Forging

The hot mechanical forming of metals between flat or shaped dies in which metal flow is not completely restricted. Also known as hand or smith forging. See also *hand forge* (*smith forge*).

O

Open-Gap Upset Welding

A form of *forge welding* in which the weld interfaces are heated with a fuel gas flame and then forced into intimate contact by the application of force. Not to be confused with *upset welding*, which is a resistance welding process.

Open-Hearth Furnace

A reverberatory melting furnace with a shallow hearth and a low roof. The flame passes over the charge on the hearth, causing the charge to be heated both by direct flame and by radiation from the roof and side walls of the furnace. See also *reverberatory furnace*.

Open-Hearth Steel

Steel made by the process of melting pig iron and steel or iron scrap in a lined regenerative furnace and boiling the mixture with the addition of pure lump iron ore until the carbon is reduced. The boiling is continued for 3–4 h. The process was developed in 1861 by Siemens in England. The furnaces contain regenerative chambers for the circulation and reversal of the gas and air. The fuels used are natural gas, fuel oil, coke-oven gas, or powdered coal. Both the acid- and the basic-lined open-hearth furnaces are used, but most steel made in the United States is basic open hearth. Ganister is used as a lining in the acid furnaces and magnesite in the basic.

An advantage of the open-hearth furnace is the ability to handle raw materials that vary greatly and to employ scrap. Iron low in silicon requires less heating time. The duplex process consists in melting the steel in an acid Bessemer furnace until the silicon, manganese, and part of the carbon have been oxidized and then transferring to a basic open-hearth furnace where the phosphorus and the remainder of the carbon are removed. Open-hearth steel is of uniform quality and is produced in practically all types.

Opening Mode

See *fracture mechanics*.

Open-Sand Casting

Any casting made in a mold that has no *cope* or other covering.

Operating Stress

The stress to which a structural unit is subjected in service.

Optical Emission Spectroscopy

Pertaining to *emission spectroscopy* in the near-ultraviolet, visible, or near-infrared wavelength regions of the electromagnetic spectrum. See also *electromagnetic radiation*.

Optical Etching

Development of microstructure under application of special illumination techniques, such as *dark-field illumination*, *phase contrast illumination*, *differential interference contrast illumination*, and *polarized light illumination*.

Optical Fibers

These are flexible transparent fiber devices, sometimes called light guides, used for either image or information transmission, in which light is propagated by total internal reflection. In its simplest form, the optical fiber or light guide consists of a core of material with a refractive index higher than the surrounding cladding. The optical fiber properties and requirements for image transfer, in which information is continuously transmitted over relatively short distances, are quite different from those for information transmission, where typically digital encoding of information into on–off pulses of light (on = 1; off = 0) is used to transmit audio, video, or data over much longer distances at high bit rates. Another application for optical fibers is in sensors, where a change in light transmission properties is used to sense or detect a change in some property, such as temperature, pressure, or magnetic field.

Fiber Designs

There are three basic types of optical fibers. Propagation in these light guides is most easily understood by ray optics, although the wave or modal description must be used for an exact description. In a multimode, step-refractive-index-profile fiber, the number of rays or modes of light that are guided, and thus the amount of light power coupled into the light guide is determined by the core size and the core-cladding refractive index difference. Such fibers, used for conventional image transfer, are limited to short distances for information transmission due to pulse broadening. An initially sharp pulse made up of many modes broadens as it travels long distances in the fiber, because high-angle modes have a longer distance to travel relative to the low-angle modes. This limits the bit rate and distance because it determines how closely input pulses can be spaced without overlap at the output end. At the detector, the presence or absence of a pulse of light in a given time slot determines whether this bit of information is a zero or one.

A graded-index multimode fiber, where the core refractive index varies across the core diameter, is used to minimize pulse broadening due to intermodal dispersion. Since light travels more slowly in the high-index region of the fiber relative to the low-index region, significant equalization of the transit time for the various modes can be achieved to reduce pulse broadening. This type of fiber is suitable for intermediate-distance, intermediate-bit-rate transmission systems. For both fiber types, light from a laser or light-emitting diode can be effectively coupled into the fiber.

A single-mode fiber is designed with a core diameter and refractive index distribution such that only one fundamental mode is guided, thus eliminating intermodal pulse-broadening effects. Material and waveguide dispersion effects cause some pulse broadening, which increases with the spectral width of the light source. These fibers are best suited for use with a laser source to couple light efficiently into the small core of the light guide and to enable information transmission over long distances at very high bit rates. The specific fiber design and the ability to manufacture it with controlled refractive index and dimensions determine its ultimate band with information carrying capacity.

Attenuation

The attenuation or loss of light intensity is an important property of the light guide because it limits the achievable transmission distance and is caused by light absorption and scattering. Every material has some fundamental absorption due to the atoms or molecules composing it. In addition, the presence of other elements as impurities can

cause strong absorption of light at specific wavelengths. Fluctuations in a material on a molecular scale cause intrinsic Rayleigh scattering of light. In actual fiber devices, fiber-core-diameter variations or the presence of defects such as bubbles can cause additional scattering light loss.

Optical fibers based on silica glass have an intrinsic transmission window at near-infrared wavelengths with extremely low losses. Such fibers are used with solid-state lasers and light-emitting diodes for information transmission, especially for long distance (greater than 1 km). Plastic fibers exhibit much higher intrinsic as well as total losses and are more commonly used for image transmission, illumination, or very short-distance data links.

Many other fiber properties are also important, and their specifications and control are dictated by the particular application. Good mechanical properties are essential for handling: plastic fibers are ductile, whereas glass fibers, intrinsically brittle, are coated with a protective plastic to preserve their strength. Glass fibers have much better chemical durability and can operate at higher temperatures than plastics.

Optical Glass

Glass of high quality and having closely specified optical properties, used in the manufacture of plane or curved windows and refractive and reflective elements for precision instruments and devices. Most products are silicates designed for maximal transmittance to the visible spectrum. Some glasses are prepared from extremely pure raw materials under special conditions to yield high ultraviolet transmission. Among infrared transmitting glasses, the chalcide glass As_2S_3 , fused silica (waterfree, mostly prepared from natural quartz), and calcium–aluminate glasses are most common. See *pyrometry*.

Optical Microscope

An instrument used to obtain an enlarged image of a small object, utilizing visible light. In general, it consists of a light source, a condenser, an objective lens, an ocular or eyepiece, and a mechanical stage for focusing and moving the specimen. Magnification capability of the optical microscope ranges from 1× to 1500×.

Optical Pyrometer

An instrument for measuring the temperature of heated material by comparing the intensity of light emitted with a known intensity of an incandescent lamp filament.

Optoelectronic Device

A device that detects and/or is responsive to electromagnetic radiation (light) in the visible, infrared, and/or ultraviolet spectra regions, emits or modifies noncoherent or coherent electromagnetic radiation in these same regions, or utilizes such electromagnetic radiation for its internal operation.

Orange Peel

A coarse-textured surface with dimples that are rounded similar to the exterior of an orange rather than angular like the surface of a cube of sugar. It is observed on badly sprayed paint or on coarse-grained sheet metal that has been deformed. In the latter case,

it results from the slightly differing deformation characteristics of neighboring grains.

Orange Peel (Ceramics)

(1) A surface condition characterized by an irregular waviness of the porcelain enamel resembling an orange skin texture; sometimes considered a defect. (2) A pitted texture of a fired glaze resembling the surface of rough orange peel.

Orange Peel (Metals)

A surface roughening in the form of a pebble-grained pattern that occurs when a metal of unusually coarse-grained size is stressed beyond its elastic limit. Also called pebbles and alligator skin.

Orange Peel (Plastics)

In injection molding of plastics, a part with an undesirable uneven surface somewhat resembling the skin of an orange.

Orbital Forging

See *rotary forging*.

Order (In x-Ray Reflection)

(1) The factor n in *Bragg's law*. In x-ray reflection from a crystal, the order is an integral number that is the path difference measured in wavelengths between reflections from adjacent planes. (2) In the context of crystal structure, it is the phenomenon in certain alloys in which the atoms of the elements in a solid solution arrange themselves in a repeated simple pattern on the atomic lattice often termed a superlattice. For example, two elements present in the appropriate proportion could position themselves at alternate sites on the 3D lattice.

Order Hardening

A low-temperature *annealing* treatment for metals that permits short-range ordering of solute atoms within a matrix, which greatly impedes dislocation motion.

Order–Disorder Transformation

A phase change among two *solid solutions* having the same crystal structure, but in which the atoms of one phase (disordered) are randomly distributed; in the other, the different kinds of atoms occur in a regular sequence upon the crystal lattice, that is, in an ordered arrangement.

Ordered Intermetallics

See *intermetallics*.

Ordered Structure

The crystal structure of a *solid solution* in which the atoms of different elements seek preferred lattice positions. Contrast with *disordered structure*.

O

Ordering

Forming a *superlattice*.

Ore

A metal-bearing mineral from which a metal or metallic compound can be extracted commercially. Earths and rocks containing metals that cannot be extracted at a profit are not rated as ores. Ores are named according to their leading useful metals. The ores may be oxides, sulfides, halides, or oxygen salts. A few metals also occur native in veins in the minerals. Ores are usually crushed and separated and concentrated from the *gangue* with which they are associated and then shipped as *concentrates* based on a definite metal or metal oxide content. The metal content to make an ore commercial varies widely with the current price of the metal and with the content of other metals present in the ore. Normally, a sulfide copper ore should have 1.5% copper in the unconcentrated ore, but if gold or silver is present, an ore with much less copper is workable, or if the deposit can be handled by high-production methods, a mineral of very low metal content can be utilized as ore. Low-grade lead minerals can be worked if silver is recoverable, and low-grade manganese minerals become commercial when prices are high. Thus, the term ore is only relative, and in other different economic conditions, minerals that are not considered ores in one country may be much used as ores in another.

Ore Dressing

A preliminary stage to the extraction of metal from an ore in which material with no metal content such as earth is removed. Same as *mineral dressing*.

Organic

Being or composed of hydrocarbons or their derivatives, or matter of plant or animal origin. Contrast with *inorganic*.

Organic Acid

A chemical compound with one or more carboxyl radicals (COOH) in its structure; examples are butyric acid, maleic acid, and benzoic acid.

Organic Coatings

Organic coatings are chiefly additive-type finishes that find use on almost all types of materials. They can be monolithic consisting simply of one layer, or coat, or they can be composed of two or more layers. The total thickness of coating systems varies widely. Some run less than 1 mil thick. Others go as high as 10 and 15 mils thick. Generally, by definition, coatings that are more than 10 mils thick are referred to as linings, films, or mastics.

To function as a protective barrier against corrosion and oxidation, organic coatings depend presently on their chemical inertness and impermeability. In addition, however, some coatings provide protection with the use of inhibiting pigments that have a passivating action, particularly on metal surfaces. Also, some coatings contain metallic pigments that give electrochemical protection to metals.

Coating Application and Drying

Organic coatings are commonly applied by the following mechanisms: (1) evaporation or loss of solvent, (2) oxidation, and (3) polymerization. After application of the coating, the volatile ingredients, which are almost always present in at least a small amount, evaporate. Some finishes, such as lacquers, dry completely by evaporation of solvents. After evaporation, coatings that do dry solely by evaporation are still in a semifluid state and depend on oxidation or polymerization, or a combination of both, to convert to their final form.

Drying by oxidation, which is usually done at room temperature, is the slowest of the three methods. Polymerization, which involves polymer chain-forming mechanism, can be done at normal or at elevated temperatures. Polymerization is speeded by use of heat. Radiation curing involving the use of an electron beam to polymerize the coating in a few seconds has found production usage.

Coating Types and Systems**Coating Composition**

An organic coating is made up of two principal components: a vehicle and a pigment. The vehicle is always there. It contains the film-forming ingredients that enable the coating to convert from a mobile liquid to a solid film. It also acts as a carrier and suspending agent for the pigment. Pigments, which may or may not be present, are the coloring agents and, in addition, contribute a number of other important properties.

Organic coatings are commonly divided into about a half-dozen broad categories based on the types and combinations of vehicle and pigment used in their formulation. They are paints, enamels, varnishes, lacquers, dispersion coatings, emulsion coatings, and latex coatings. However, with the complexity in modern formulations, distinctions between these various types are often difficult to make.

As mentioned earlier, organic finish systems are frequently composed of more than one layer or coat. These various layers are commonly classified as primers, intermediate coats, and finish coats.

Primers

These are the first coatings placed on the surface (except for fillers, in some cases). Where chemical pretreatments are used, primer coats may often be unnecessary. Primers for industrial or production finishing are of two types: air-dry types and baking types. The air-dry types have drying oil vehicle bases and are usually referred to as paints. They may or may not be modified with resins. They are not used as extensively as the baking-type primers, which have resin or varnish vehicle bases and dry chiefly by polymerization. Some primers, known as flash primers, are applied by spraying and dry by solvent evaporation within 10 min. In practically all primers, the pigments impart most of the anticorrosion properties to the primer and, along with the vehicle, determine its compatibility and adherence with the base metal.

Intermediate Coats

These are fillers, surfacers, and sealers. They can be applied either before or after the primer, but more often after the primer and sometimes after the surfacer coat. Their function is to fill in large irregularities in the surface or local imperfections. They are usually puttylike substances, and a variety of materials are used. Their chief characteristics are as follows: (1) must harden with a minimum

shrinkage, (2) must have good adhesion, (3) must have good sanding properties, and (4) must work smoothly and easily.

Surfacers are often similar to primers; they usually have the same composition as the priming coat, except that more pigment is present. Surfacers are applied over the priming coat to cover all minor irregularities in the surface. Sealers as a rule are used over either the fillers or surfacers. The chief function of sealers is to fill up the pores of the undercoat to avoid “striking in” of the finish coats. This filling in of the porous surfacer or sealer also tends to strengthen the entire coating system. The sealers when used over surfacers are usually formulated with the same type pigment and vehicle as used in the final coat.

Finish Coats

Finish or top coats are usually the decorative or functional part of a paint system. However, they often also have a protective function. The primer coats may require protection against the service conditions, because although the pigments used in primers are satisfactory for corrosion protection of the metal, they are frequently not satisfactory as top coats. Their color retention upon weathering or their physical durability may be poor. There are also one-coat applications where the finish coats are applied directly to the base material surface and, therefore, provide the sole protective medium.

Vehicles

Vehicles are composed of film-forming materials and various other ingredients, including thinners (volatile solvents), which control viscosity, flow, and film thickness, and driers, which facilitate applications and improve drying qualities.

The main concern is chiefly the film-forming part of the vehicle, because it is that part of the vehicle that to a large extent determines the quality and character of an organic finish. It determines the possible ways in which the finish can be applied and how the “wet” finish will dry to a hard film; it provides for adhesion to the metal surface; and it usually influences the durability of the finish.

Vehicles can be divided into three main types: (1) oil, (2) resin, and (3) varnish. The simplest and among the oldest vehicles are the straight drying oil types. Resins, as a class, can serve as vehicles in their own right or can be used with drying oils to make varnish-type vehicles. Varnish vehicles are composed of resins and either drying or nondrying oils, together with required amounts of thinners and driers. They are often used alone as a full-fledged organic finish.

Drying Oils

Vehicles consisting of oil only are used to a limited extent in industrial finishes. Linseed oil is probably the most widely used oil. There are a number of different kinds that differ in rate of drying and in such properties as water resistance, color, and hardness.

Tung oil or China wood oil, when properly treated, excels all other drying oils and speed of drying, hardening, and water resistance. Oiticica oil is similar to tung oil in many of its properties. Dehydrated castor oil dries better than linseed oil, but slower than tung oil. Some of its advantages are good color and color retention and flexibility. The oils from some fish are also used as drying oils. If processed properly, they dry reasonably well and have little odor. They are often used in combination with other oils. Perilla oil is quite similar in properties to fast-drying linseed oil. Its use is largely dependent upon its price and availability.

Soybean oil has the slowest drying rate in the drying oil classes and is usually used in combination with some faster-drying oils such as linseed oil.

Resins

Although both natural and synthetic resins can serve as organic coating vehicles, today the natural types, such as rosin, have been largely replaced by plastic resins. Nearly all the plastic resins—both thermosets and thermoplastics as well as many elastomers—can be used as film formers, and frequently two or more kinds are combined to give the set of properties desired. Typical thermoplastics used in vehicles are acrylics, acetates, butyrates, and vinyls. Commonly used thermosets for vehicles include phenolics, alkyds, melamines, ureas, and epoxies.

Pigments

Pigments are the second of the two principal components that make up most organic finishes. They contribute a number of important characteristics to a coating. They, first of all, serve a decorative function. The choice of color and shades of color by use of one or combinations of pigments are practically unlimited. Closely associated with color is the hiding power function or their ability to obscure the surface of the material being finished. In many primers, the principal function of pigments is to prevent corrosion of the base metal. In other cases, they may be added to counteract the destructive action of ultraviolet light rays. Pigments also help give body and good flow characteristics to the finish. And, finally, some pigments may give to organic coatings what is termed package stability, that is, they keep the coating material in usable condition in the container until ready for use.

Pigments can be conveniently divided into three classes as follows: (1) white hiding pigments, (2) colored pigments, and (3) extender or inert pigments. White pigments are used not only in making white paints and enamels but also in making white bases for the tinted and light shades. Colored pigments furnish the finish with both opacity and color. They may be used by the cells to form solid colors, or in combination with whites to produce tints, and often provide rust-inhibitive properties. For example, red lead, certain lead chromates, zinc chromates, and blue lead are used in iron and steel primers as rust inhibitors. There are two general classes of colored pigments—earth colors, which are very stable and are not readily affected by acids and alkalis, heat, light, and moisture, and chemical colors, which are produced under control conditions by chemical reaction. The metallic pigments can also be included within this class. Aluminum powder is perhaps the best known.

The chief functions of extender pigments are to help control consistency, gloss, smoothness, and filling qualities and leveling and check resistance. Thus, particle size and shape, oil absorption, and flattening power are important selection considerations. Extender pigments are for the most part chemically inactive. They usually have little or no hiding power.

Enamels

By definition, enamels are an intimate dispersion of pigments in a varnish or a resin vehicle or in a combination of both. Enamels may dry by oxidation at room temperatures and/or by polymerization at room or elevated temperatures. They vary widely in composition, in color and appearance, and in properties and are available in all

colors and shades. Although they generally give a high-gloss finish, there are some that give a semigloss or eggshell finish and still others that give a flat finish. Enamels as a class are hard and tough and offer good mar and abrasion resistance. They can be formulated to resist attack of most commonly encountered chemical agents in corrosive atmospheres.

Because of their wide range of useful properties, enamels are probably the most widely used organic coating in industry. One of their largest fields of use is for coating household appliances—washing machines, stoves, kitchen cabinets, and the like. A large portion of refrigerators, for example, are finished with synthetic baking enamels. These appliance enamels are usually white, and, therefore, most have a high degree of color and gloss retention when subjected to light and heat. Other products finished with enamels include automotive products, railway equipment, office equipment, toys and sports supplies, industrial equipment, and novelties.

Lacquers

The word *lacquer* comes from lac resin, which is the base of common shellac. Lac resin dissolved in alcohol was one of the first lacquers and has been in use for many centuries. Nowadays, shellac is called spirit lacquer. It is only one of several different kinds of lacquers; these, except for spirit lacquer, are named after the chief film-forming ingredient. The most common ones are cellulose acetate, cellulose acetate butyrate, ethyl cellulose, vinyl, and nitrocellulose.

A distinguishing characteristic of lacquers is that they dry by evaporation of the solvents or thinners in which the vehicle is dissolved. This is in contrast to oils, varnishes, or resin base finishes, which are converted to a hard film chiefly through oxidation or polymerization.

Because many modern lacquers have high resin content, the gap between lacquer and synthetic-type varnishes diminishes until finally one has modified synthetic air-drying varnishes. They may dry chiefly by oxidation or polymerization.

Lacquers normally dry hard and dust-free in a very few minutes at room temperature. In production line work, forced drying is often used. It is possible, therefore, to do a multicoat job without having to lose time between coats. Because of the speed of drying and the fact that they are permanently soluble in the solvents used for application, lacquers usually are not applied by brush. Spray application or dipping is the usual procedure.

Lacquers can be either clear and transparent or pigmented, and the color range is practically unlimited. Lacquers in themselves have good color retention, but sometimes the added pigments, modifying resins, and plasticizers may adversely affect this property. They are hard and mar resistant. Inherently, they lack good adhesion to metal, but modern lacquer formulations have greatly improved their adhesion properties. Lacquers can be made to be resistant to a large variety of chemicals, including water and moisture, alcohol, gasoline, vegetable oil, animal and mineral oils, and mild acids in alkalis. Because of the volatile solvents, lacquers are inflammable in storage and during application, and this sometimes limits their application.

Because of their fast drying speeds, lacquers find wide application in the protection and decoration of products that can be dipped, spray, roller coated, or flow coated. They are especially advantageous for coating metal hardware and fixtures, toys, and other articles that, because of volume production, must dry hard enough to handle and pack in a short period of time. Lacquers

are widely used in automobile finishing and especially for refinishing autos and commercial vehicles where fast drying without baking equipment is a requirement. Lacquers also compete with enamels for coating metal stampings and castings, including die castings.

Varnishes

Varnishes consist of thermosetting resins and either drying or non-drying oils. They are clear and unpigmented and can be used alone as a coating. However, their major use in industrial finishing is as a vehicle to which pigments are added, thus forming other types of organic coatings.

The drying mechanisms of varnishes all follow the same general pattern. First, any volatile solvents that are present evaporate; then, drying by oxidation and/or polymerization takes place, depending on the nature of the resin and oil. At high temperatures, of course, there is more tendency to polymerize. So, varnishes can be formulated for either air or bake drying. Varnishes may be applied by brushing or by any of the production methods.

It is evident that with the large variety of raw materials to choose from and the unlimited number of combinations possible, varnishes have an extensive range of properties and characteristics. They range from almost clear white to a deep gold; they are transparent, lacking any appreciable amount of opacity. Japan, a hard-baked black-looking varnish, is an exception. It is opaque, due to carbon and carbonaceous material being present.

There are some distinctions in properties between oil-modified alkyd varnishes and the other types. In general, oil-modified alkyds have better gloss and color retention and better resistance to weathering. They form a harder, tougher, more durable film and dry faster. On the other hand, they have less alkali resistance than the other varnishes. In such things as adhesion and inhibiteness, there is no distinctive difference.

The major use of varnishes, as coatings in their own right, is for food containers, closures such as bottle caps, and bandings of various kinds. Another large application is as a clear finish coat over lithographic coatings.

Paints

The word *paints* is sometimes used broadly to refer to all types of organic coatings. However, by definition, a paint is a dispersion of a pigment or pigments in drying oil vehicle. They find little use these days as industrial finishes. Their principal use is for primers. Paints dry by oxidation at room temperature. Compared to enamels and lacquers, their drying rate is slow; they are relatively soft and tend to chalk with age.

Other Organic Coatings

Dispersion and Emulsion Coatings

In recent years, these coatings have become known as water-based paints or coatings because many of them consist essentially of finely divided ingredients, including plastic resins, fillers, and pigments, suspended in water. An organic media may also be involved. There are three types of water-based coatings. Emulsions, or latexes, are aqueous dispersions of high-molecular-weight resins. Strictly speaking, latex coatings are dispersions of

resins in water, whereas emulsion coatings are suspensions of an oil phase in water.

Emulsion and latex coatings are clear to milky in appearance and have low gloss, excellent resistance to weathering, and good impact resistance. Chemical and stain resistance varies with composition. Dispersion coatings consist of ultrafine fine, insoluble resin particles present as a colloidal dispersion in an aqueous medium. They are clear or nearly clear. Weathering properties, toughness, and gloss are roughly equal to those of conventional solvent paints.

Water-soluble types, which contained low-molecular-weight resins, are clear finishes, and they can be formulated to have a high gloss, fair to good chemical and weathering resistance, and high toughness. Of the three types, they handle and flow most like conventional solvent coatings.

Plastic Powder Coatings

Several different methods have been developed to apply plastic powder coatings. In the most popular process—fluidized bed—parts are preheated and then immersed in a tank of finely divided plastic powders, which are held in a suspended state by a rising current of air. When the powder particles contact the heated part, they fuse and adhere to the surface, forming a continuous, uniform coating.

Another process, electrostatic spraying, works on the principle that oppositely charged materials attract each other. Powder is fed through a gun, where an electrostatic charge is applied opposite that applied to the part to be coated. When the charged particles leave the gun, they are attracted to the part where they cling until fused together as a plastic coating. Other powder application methods include flock coating, flow coating, flame and plasma spraying, and a cloud chamber technique.

Although many different plastic powders can be applied by these techniques, vinyl, epoxy, and nylon are most often used. Vinyl and epoxy provide good corrosion and weather resistance as well as good electrical insulation. Nylon is used chiefly for its outstanding wear and abrasion resistance. Other plastics frequently used in powder coating include chlorinated polyether, polycarbonate, acetal, cellulotics, acrylic, and fluorocarbons.

Hot Melt Coatings

These consist of thermoplastic materials that solidify on the metal surface from the molten state. The plastic is either applied in solid form and then melted and flowed over the surface or is applied molten by spraying or flow coating. Since no solvent is involved, fixed single coats are possible. Bituminous coatings are also commonly applied by the hot melt process.

Lining and Sheeting

Sheet, film, and tapes of various plastics and elastomers cemented to material shapes and parts are used to provide corrosion and abrasion resistance. Thickness usually ranges from 3.2 to 12.7 mm. The most widely used materials are polyvinyl chloride, polyethylene butadiene–styrene rubber, and neoprene.

Specialty Finishes

An almost infinite number of specialty or novelty finishes are available. Most of them are really lacquers or enamels to which special ingredients have been added or which are processed in some unique way to give the effects desired.

One of the most common types is those giving a roughened or wrinkled appearance, which is obtained by the use of high percentages of driers causing wrinkling when the finish is baked. Another group of specialty finishes gives a crystalline effect. They are enamels in which impurities are purposely introduced during the baking process by retaining the products of combustion in the oven while the coating dries. The wrinkle and crystalline finishes are widely used on instrument panels, office equipment, and a variety of other industrial and consumer products.

Other unusual finishes are obtained by adding special ingredients to lacquers that give them a stringy or “veiled” appearance when applied by spraying. The application of the silk-screen process to organic finishing of metals has also resulted in unique finishes with multicolored effects.

Organic Fiber

A fiber derived or composed of matter originating in plant or animal life or composed of chemicals of hydrocarbon origin, either natural or synthetic.

Organic Zinc-Rich Plant

Coating containing zinc powder pigment and an *organic* resin.

Organometallic Compounds

These are members of a broad class of compounds with structures that contain both carbon (C) and a metal (M). Although not a required characteristic of organometallic compounds, the nature of the formal carbon–metal bonds can be of the covalent type.

The term *organometallic* chemistry is essentially synonymous with organotransition metal chemistry; it is associated with a specific portion of the periodic table ranging from groups 3 through 11 and also includes the lanthanides.

This particular area has experienced exceptional growth since the mid-1970s largely because of the continuous discovery of novel structures as elucidated mainly by x-ray crystallographic analyses, the importance of catalytic processes in the chemical industry, and the development of synthetic methods based on transition metals that focus on carbon–carbon bond constructions. From the prospective of inorganic chemistry, organometallics afford seemingly endless opportunities for structural variations due to changes in the metal coordination number, alterations in ligand–metal attachments, mixed-metal cluster formation, and so forth. From the viewpoint of organic chemistry, organometallics allow for manipulations in the functional groups that in unique ways often result in rapid and efficient elaborations of carbon frameworks for which no comparable direct pathway using non-transition organometallic compounds exists.

As one moves across the periodic table, the metals that have found application include

- Titanium
- Zirconium
- Chromium
- Molybdenum
- Tungsten
- Ruthenium
- Osmium

O

- Cobalt
- Rhodium
- Palladium
- Copper

Of interest to the ceramic industry are those organometallics, the hydroxide-free alkoxides, that can be used for the vapor-phase synthesis of hard ceramic oxide coatings, films, or free-standing bodies. Very fine particulate oxides also can be formed from these chemicals.

Compounds now available include aluminum isopropoxide, aluminum hexafluoroisopropoxide, lithium hexafluoroisopropoxide, sodium hexafluoroisopropoxide, zirconium hexafluoroisopropoxide, and zirconium tertiary amyloxide.

Organosol

A suspension of a finely divided resin in a volatile, organic liquid. The resin does not dissolve appreciably in the organic liquid at room temperature but does at elevated temperatures. The liquid evaporates at an elevated temperature, and the residue upon cooling is a homogenous plastic mass. Plasticizers may be dissolved in the volatile liquid.

Organosol Coatings

Organosol coatings are coatings in which the resin (usually polyvinyl chloride) is suspended rather than dissolved in an organic fluid. The dispersion technique permits the use of high-molecular-weight, relatively insoluble resins without the use of expensive solvents. In organosols, the fluid, or dispersant, consists of plasticizers together with a blend of inexpensive volatile diluents selected to give the desired fluidity, speed of fusion, and physical properties. The dispersant provides little or no solvating action on the resin particles until a critical temperature is reached at which point the resin is dissolved in the dispersant to form a single-phase solid solution. Since a portion of a liquid is made up of volatile diluents, diffusion process results in a proportional shrinkage. (Nonvolatile dispersions using only plasticizer dispersants are termed *plastisols*.)

Organosols are available with a wide range of flow characteristics and consequently may be formulated for application by any of the conventional techniques. Because they contain substantial quantities of volatile diluents, their thickness is limited to 10–12 mils per coat. Single-coat applications of greater thickness blister during baking are a result of trapped solvents.

Baking is generally accomplished in two stages. The volatiles are removed in the first stage at temperatures of 93°C–121°C, but fusion does not occur until a temperature of 149°C–191°C is reached. The fusion stage accomplishes the union of the discrete vinyl particles into a single-phase solid. In addition to polyvinyl chloride, the organosol technique can be used with acrylonitrile-vinyl and polychlorotrifluoroethylene resins. A balance must be achieved in the baking operation between the removal of the volatiles and the solvation of the resins. Rapid heating results in solvent blistering, whereas the reverse causes a mud-cracking effect.

Application Methods

Organosol coatings can be applied by several methods.

Spread Coating

The bulk of the organosols is applied by spread coating methods to fabrics and paper. Several plants are used as spread coaters for the application of organosols and plastisols to strip steel to provide materials competitiveness with the light metals and plastics. Two basic processes are available: the knife coater and the roll coater. Knife coating is simple and fast, but the product lacks uniformity afforded by roller coating. Fusion is accomplished in a tunnel oven, and embossing rolls may be employed at the oven exit to impart a texture or pattern to the hot-gelled coating.

Strand Coating

Wires or filaments may be coated with organosols by first passing the strand through a dip tank and then through a wiping die to set the thickness. Fusion is accomplished in a drying tower. As many as 9–10 passes may be required to build a thickness of 20 mils.

Dip Coating

One of the major problems encountered in dip coating with organosols is the tendency of dried organosol to fall back into the dip tank and cause coating rejects. For this reason, much of the dip coating is done with modified plastisols rather than organosols. A dipping formulation must have low viscosity with high yield value to prevent sags and drains. The rate at which the article is withdrawn from the dip tank is a determining factor in the thickness and quality of deposit. Withdrawal rates generally range between 1.7 and 5.5 mm/s. Special techniques such as inversion of the dipped article just prior to fusion may be employed to alleviate the drip problem when it is particularly troublesome.

Spray Coating

Organosols are readily handled in either suction or pressure spray equipment. For production-line spraying, pressure systems afford rapid delivery and are generally preferred. There is an increasing tendency to use electronic spray processes for handling organosols. A number of electrostatic processes are available including several "handguns."

Properties

Organosols have the characteristic vinyl properties of toughness and moisture resistance. However, although the coatings possess good electrical resistance and are frequently used as secondary insulation to reduce shock hazards, they seldom meet the needs of primary wire insulation. Adhesive primers are required to bond the materials to metals and other dense substrates. Prolonged exposure to temperatures greater than 93°C causes thermal degradation, which is generally evidenced by a gradual darkening.

Uses

Vinyl organosols have found their widest usage in the coating of paper and fabric stock where their ease of handling has permitted the use of simplified, low-cost application equipment. Where fabric coating strike-through is to be avoided, as in open weave, thixotropic plastisols are employed rather than organosols. Closer weaves require some penetration.

Textured finishes for metals are a growing use and offer competition to the vinyl laminates and other decorative finishes.

Typical applications and related properties of organosols are shown in the following.

Application	Related Properties
<i>Automotive interiors:</i> Station-wagon flooring, roof liners, dashboards, cowlings, kick plates	Ease of application; uniformity of color and texture; resistance to gasoline, grease, and polishes; resistance to impact damage
<i>Commercial vehicles:</i> Seatbacks, trim, interior paneling, luggage racks, sill plates	<i>Durability:</i> Resistance to abrasion and scuffing; cleanability; resistance to moisture and staining
<i>Appliance finishes:</i> Television and radio cabinets, slide projectors, refrigerator panels	<i>Aesthetic qualities:</i> Novelty of appearance; durability; resistance to abrasion and scratching; resistance to moisture and staining
<i>Business machines:</i> Typewriters, calculators, electronic computers, laboratory instruments	<i>Durability:</i> Resistance to abrasion, scuffing, and chipping; resistance to chemicals and perspiration; sound-deadening qualities
<i>Architectural applications:</i> Paneling, partitions, shower stalls, elevator doors, bathroom wall sections	<i>Cleanability:</i> Resistance to moisture and detergents; aesthetic qualities; durability; resistance to abrasion and scuffing; sound-deadening qualities
<i>Office furniture:</i> Desks, file cabinets, showcases, counters, wastebaskets, chair finishes	<i>Durability:</i> Resistance to abrasion, impact, and scuffing; resistance to moisture and staining
Luggage	<i>Durability:</i> Toughness, resistance to abrasion and scuffing; aesthetic qualities
<i>Paper and fabrics:</i> Floor and wall coverings, place mats, bottle-cap liners, containers for food packaging, bandage dressings, upholstery fabrics, safety clothing, glove coatings	<i>Ease of application:</i> Economy and simplicity of application equipment; resistance to abrasion and tearing; resistance to moisture and staining
<i>Glass coatings:</i> Perfume bottles, bleach and chemical reagent bottles, photo flash bulbs	Resiliency, feel, cohesion strength; resistance to alcohol, moisture, and chemicals; ease of application

Orientation

The alignment of some feature relative to its surroundings, for example, in a metallurgical context, the alignment of the crystal lattice relative to the axis of the material. In an as-cast material, the orientation of the lattice in individual grains will, in most cases, be random, but working processes such as rolling tend to bring the orientation of all grains into alignment. This is termed *preferred orientation*. It causes properties such as ductility to vary in different directions. For example, a rolled sheet may have more ductility in the direction of rolling than at an angle of 45° to the rolling direction. This can cause problems in processes such as deep drawing.

Orientation (Crystal)

Arrangements in space of the axes of the lattice of a crystal with respect to a chosen reference or coordinate system. See also *preferred orientation*.

Orientation (Plastics)

The alignment of the crystalline structure in polymeric materials to produce a highly aligned structure. Orientation can be accomplished by cold drawing or stretching and fabrication. Orientation can generally be divided into two classes: uniaxial and biaxial.

Oriented Materials (Plastics)

Polymeric materials with molecules and/or macroconstituents that are aligned in a specific way. Oriented materials are anisotropic.

Orifice Gas

In plasma arc welding and cutting, the gas that is directed into the torch to surround the electrode. It becomes ionized in the arc to form the plasma and issues from the orifice in the torch nozzle as the plasma jet. See the terms *nontransferred arc* and *plasma arc welding*.

Original Crack Size (α_0)

The physical crack size at the start of testing.

Orsat Analyzer

A furnace atmosphere analysis device in which gases are absorbed selectively (volumetric basis) by passing them through a series of preselected solvents.

Orthochromatic

Sensitive to all colors except orange and red.

Orthorhombic

Having three mutually perpendicular axes of unequal lengths.

Orthotropic

Having three mutually perpendicular planes of elastic symmetry.

Oscillating Die Press

A small high-speed metal forming press in which the die and punch move horizontally with the strip during the working stroke. Through a reciprocating motion, the die punch returns to their original positions to begin the next stroke.

Osmiridium

An alloy felt as a native metal is platinum ore. As the name indicates, it is predominantly osmium (about 30%–40%) and iridium (about 50%–60%) with, usually, some lead as well as other elements

O

of the platinum group. It is very hard and wear resistant and is used for small high-value applications such as pen tips.

Osmium

A platinum-group metal, symbol Os, osmium is noted for its high hardness, about 400 Brinell. The heaviest known metal, it has a high specific gravity, 22.65, and a high melting point, 2698°C. The boiling point is about 5468°C. Osmium has a close-packed hexagonal crystal structure and forms solid solution alloys with platinum, having more than double the hardening power of iridium in platinum. However, it is seldom used to replace iridium as a hardener except for fountain-pen tips where the alloy is called *osmiridium*.

Osmium is not affected by the common acids and is not dissolved by aqua regia. It is practically unworkable, and its chief use is as a catalyst.

Uses

Osmium tetroxide, a commercially available yellow solid (melting point 40°C), is used commercially as a stain for tissue in microscopy. It is poisonous and attacks the eyes. Osmium metal is catalytically active, but it is not commonly used for this purpose because of its high price. Osmium and its alloys are hard and resistant to corrosion and wear (particularly to rubbing wear). Alloyed with other platinum metals, osmium has been used in needles for record players, fountain-pen tips, and mechanical parts.

Osmosis

The percolation of solvent through a semipermeable membrane into a more concentrated solution so that the concentrations on the two sides of the membrane tend to equalize.

Osprey Spray Forming

Copper alloy semifinished products, made by the Osprey spray-forming process, feature the ability to combine properties such as high strength, good corrosion resistance, and excellent machinability.

In the Osprey process, powder particles are liquefied and sprayed by an inert gas onto a substrate, where they are shaped into a billet. Because the droplets solidify very rapidly, the microstructure is much finer than that of conventionally cast material.

For example, the high yield strength and low elastic modulus of Cu-14%–Sn alloy (with a small lead addition) make this alloy (BO5) ideal for spring applications. Its elastic modulus is 80–90 GPa, yield strength is 800–950 MPa, and ultimate tensile strength is 900–1000 MPa, with hardness of 240–280 HV.

For the fabrication of contact elements by stamping and bending, alloy Cu-15%–Ni-8%–Sn (CN8) would be a good choice. It has elastic modulus of 110–120 GPa, yield strength of 800–1300 MPa, ultimate tensile strength of 900–1400 MPa, and hardness of 240–400 HV.

Out of Position Welding

Any position other than flat.

Out Time

The time a *prepreg* is exposed to ambient temperature, namely, the total amount of time the prepreg is out of the freezer. The primary effects of out time or a decrease in the *drape* and *tack* of the prepreg and the absorption of moisture from the air.

Outgassing

(1) The release of adsorbed or occluded gases or water vapor, usually by heating, as from a vacuum tube or other vacuum system. (2) Devolatilization of plastics or applied coatings during exposure to vacuum in vacuum metallizing. Resulting parts show voids or thin spots in plating with reduced and spotty brilliance. Additional drying prior to metallizing is helpful, but outgassing is inherent to plastic materials and coating ingredients, including plasticizers and volatile components.

Outlier

In a set of data, a value so far removed from other values in the distribution that is probably not a bona fide measurement. There are statistical methods for classifying a data point as an outlier and removing it from a data set.

Ovaloid

A surface of revolution symmetrical about the polar axis that forms the end closure for a filament-wound cylinder.

Oven Dry

The condition of a plastic material that has been heated under prescribed conditions of temperature and humidity until there is no further significant changes in its mass.

Oven Soldering

See preferred term *furnace soldering*.

Ovenware

Glass and glass–ceramic materials able to withstand thermal down-shock of 150°C (270°F) without breakage that are used for culinary oven use. See *glass* and *glass ceramics*.

Overaging

Aging under conditions of time and temperature greater than those required to obtain maximum change in a certain property, so that the property is altered in the direction of the initial value. See *precipitation hardening*.

Overbasing

A technique for increasing the basicity of lubricants. Overbased lubricants are used to assist in neutralizing acidic oxidation products.

Overbending

Bending metal through a greater arc than that required in the finished part to compensate for springback.

Overdraft

A condition wherein a metal curves upward on leaving the rolls because of the higher speed of the lower roll.

Overfill

The fill of a die cavity with an amount of powder in excess of specification.

Overglaze

A glass coating over another component or element, normally used to give physical or electrical protection.

Overhead Welding Position

The position in which the weld run is approximately horizontal but is made from beneath the components. This is usually taken to mean a weld slope not greater than 15° and a weld rotation between 168° and 180° for a butt weld and between 115° and 180° for a fillet.

Overhead-Drive Press

A mechanical press with the driving mechanism mounted in or on the crown or upper parts of the uprights. See the term *straight-side press*.

Overheating

Heating a metal or alloy to such a high temperature that its properties are impaired. When the original properties cannot be restored by further heat treating, by mechanical working, or by a combination of working and heat treating, the overheating is known as *burning*.

Overlap

(1) Pultrusion of weld metal beyond the toe, face, or root of a weld. (2) In resistance seam welding, the area in a given weld remelted by the succeeding weld. (3) A weld defect caused by molten metal running onto adjacent parent metal but not fusing to it. See also *face of weld*, *root of weld*, and *toe of weld*.

Overlay Sheet

A nonwoven fibrous mat (e.g., of glass synthetic fiber) used as the top layer in a cloth or mat *layup* to provide a smoother finish, minimize the appearance of the fibrous pattern, or permit machining or grinding to a precise dimension. Also called *surfacing mat*.

Overlaying

See preferred term *surfacing*.

Overmix

Mixing of a powder longer than necessary to produce adequate distribution of powder particles. Overmixing may cause particle size segregation.

Oversinter

The sintering of a powder compact at higher temperature or for longer time periods than necessary to obtain the desired microstructure or physical properties. It often leads to swelling due to excessive pore formation.

Oversize Powder

Powder particles larger than the maximum permitted by a particle size specification.

Overspray

The excess spray material that is not deposited on the part during *thermal spraying*.

Overstraining

The application of a strain beyond yield particularly where this is deliberate to develop beneficial residual stresses.

Overstressing

(1) In fatigue testing, cycling at a stress level higher than that used at the end of the test. (2) Any excessive stress but particularly the damaging application of one or more cycles of fatigue with a stress in excess of the fatigue limit.

Overvoltage

The difference between the actual electrode potential when appreciable electrolysis begins and the reversible electrode potential.

Oxalic Acid

Also known as *ethane diacid*. A strong organic acid that crystallizes as the ortho acid. It reduces iron compounds and is thus used in writing inks, stain removers, and metal polishes. When it absorbs oxygen, it is converted to the volatile carbon dioxide and to water, and it is used as a bleaching agent, as a mordant in dyeing, and in detergents. Oxalic acid occurs naturally in some vegetables, notably *Swiss chard*, and is useful in carrying off excess calcium in the blood. The acid is produced by heating sodium formate and treating their resulting oxides with sulfuric acid, or it can be obtained by the action of nitric acid on sugar or strong alkalies on sawdust. It comes in colorless crystals with a specific gravity of 1.653, containing about 71% of the anhydrous acid, and soluble in water and alcohol. It is used in metal cleaning, dyeing, photography, and pulp bleaching. *Oxamide* is a stable anhydrous derivative with a high melting point 786°F (419°C). It is a white crystalline powder used in flame proofing and in wood treatment. Potassium ferric oxalate, $K_3Fe(C_2O_4)_3$, is stable in the dark but is reduced by the action of light and is used in photography.

O

Oxidation

In its metallurgical sense, the reaction of a metal with oxygen to form its oxide. In its electrochemical sense, the loss of electrons from a metal during any chemical reaction. The term encompasses a wide range of reaction rates, extending from the slow surface oxidation of iron in air, through burning to explosions.

Oxidation (Carbon Fibers)

In carbon/graphite fiber processing, the step of reacting the precursor polymer (rayon, polyacrylonitrile, or pitch) with oxygen, resulting in stabilization of the structure for the hot stretching operation.

Oxidation (Metals)

(1) A reaction in which there is an increase in valence resulting from a loss of electrons. Contrast with *reduction*. (2) A corrosion reaction in which corroded metal forms an oxide; usually applied to reaction with a gas containing elemental oxygen, such as air. (3) A chemical reaction in which one substance is changed to another by oxygen combining with the substance. Much of the dross from holding and melting furnaces is the result of oxidation of the alloy held in the furnace.

Oxidation Grain Size

(1) Grain size determined by holding a metallic specimen at a suitably elevated temperature in a mildly oxidizing atmosphere. The specimen is polished before oxidation and etched afterward. (2) Refers to the method involving heating a polished steel specimen to a specified temperature, followed by quenching and repolishing. The grain boundaries are sharply defined by the presence of iron oxide.

Oxidation Losses

Reduction in the amount of metal or alloy through *oxidation*. Such losses are usually the largest factor in melting loss.

Oxidative Wear

(1) A *corrosive wear* process in which chemical reaction with oxygen or oxidizing environment predominates. (2) A type of *wear* resulting from the sliding action between two metallic components that generate oxide films on the metal surfaces. These oxide films prevent the formation of a metallic bond between the sliding surfaces, resulting in fine wear debris and low rates. See also *fretting*.

Oxide

A compound of any element with oxygen. The manner in which metals form oxides determines the corrosion characteristics of a metal. The noble metals such as gold do not readily form oxides and hence are considered corrosion resistant. Other metals such as aluminum are highly reactive with oxygen and hence form an oxide film as soon as they are exposed to air. However, the oxide film is thin, tenacious, and impervious to oxygen and so further attack is stifled. Such metals, which include aluminum, titanium, and chromium, are also regarded as corrosion resistant in the environments in which

the protective oxide is formed and maintained. Finally, some metals such as iron in a moist environment react with oxygen to form an oxide that is bulky, cracks, and is readily detached so it does not significantly impede continued attack.

Oxide Ceramics

Oxide ceramics can be divided into two groups—single oxides that contain one metallic element and mixed or complex oxides that contain two or more elements. Examples include alumina, beryllia, magnesia, zirconia, and thoria. As a class, they are low in cost compared to other technical ceramics, except for thoria and beryllia. Each of them can be produced in a variety of compositions, porosity, and microstructure, to meet specific property requirements.

Oxide ceramic parts are produced by slip casting or pressing or extrusion and then fired at about 1800°C. They are more difficult to fabricate than other types of ceramics, because of the usual requirement to obtain a high-density body with minimum distortion and dimensional error, except in the case of porous bodies for use as thermal insulation. Powder pressing produces bodies with the lowest porosity and higher strength, because of the high pressures and the small amount of binder required.

Single Oxides**Aluminum Oxide (Alumina)**

Alumina is the most widely used oxide, chiefly because it is plentiful, relatively low in cost, and equal to or better than most oxides in mechanical properties. Density can be varied over a wide range, as can purity—down to about 90% alumina—to meet specific application requirements. Alumina ceramics are the hardest, strongest, and stiffest of the oxides. They are also outstanding and with electrical resistivity and dielectric strength, are resistant to a wide variety of chemicals, and are unaffected by air, water vapor, and sulfurous atmospheres. However, with a melting point of only 2039°C, they are relatively low in refractoriness and at 1371°C retain only about 10% of room-temperature strength. In addition to its wide use as electrical insulators and its chemical and aerospace applications, the high hardness and close dimensional tolerance capability of alumina make this ceramic suitable for such abrasion-resistant parts as textile guides, pump plungers, chute linings, discharge orifices, dies, and bearings.

Beryllium Oxide (Beryllia)

Beryllia is noted for its high thermal conductivity, which is about 10 times that of a dense alumina (at 499°C), three times that of steel, and second only to that of the high-conductivity metals (silver, gold, and copper). It also has high strength and good dielectric properties. However, beryllia is costly and is difficult to work with. Above 1649°C, it reacts with water to form a volatile hydroxide. Also, because beryllia dust and particles are toxic, special handling precautions are required. The combination of strength, rigidity, and dimensional stability makes beryllia suitable for use in gyroscopes; and because of high thermal conductivity, it is widely used for transistors, resistors, and substrate cooling in electronic equipment.

Magnesium Oxide (Magnesia)

Magnesia is not as widely useful as alumina and beryllia. It is not as strong, and because of high thermal expansion, it is susceptible to thermal shock. Although it has better high-temperature oxidation

resistance than alumina, it is less stable in contact with most metals at temperatures above 1705°C in reducing atmospheres or in a vacuum.

Zirconium Oxide (Zirconia)

There are several types of zirconia: a pure (monoclinic) oxide and a stabilized (cubic) form and a number of variations such as yttria- and magnesia-stabilized zirconia and nuclear grades. Stabilized zirconia has a high melting point, about 2760°C, low thermal conductivity, and is generally unaffected by oxidizing and reducing atmospheres and most chemicals. Yttria- and magnesia-stabilized zirconias are widely used for equipment and vessels in contact with liquid metals. Monoclinic nuclear zirconia is used for nuclear fuel elements, reactor hardware, and related applications where high purity (99.7%) is needed. Zirconia has the distinction of being an electrical insulator at low temperatures, gradually becoming a conductor as temperatures increase.

Thorium Oxide (Thoria)

Thoria, the most chemically stable oxide ceramic, is only attacked by some earth alkali metals under some conditions. It has the highest melting point (3315°C) of the oxide ceramics. Like beryllia, it is costly. Also, it has high thermal expansion and poor thermal shock resistance.

Mixed Oxides

Cordierite ($2\text{MgO} \cdot 2\text{Al}_2\text{O}_3 \cdot \text{ASiO}_2$)

Cordierite is most widely used in extruded form for insulators such as heating elements and thermocouples. It has low thermal expansion, excellent resistance to thermal shock, and good dielectric strength. There are three traditional groups of cordierite ceramics:

1. Porous bodies that have relatively little mechanical strength due to limited crystalline intergrowth and absence of ceramic bond. With long thermal endurance and low thermal expansion, they are used for radiant elements in furnaces, resistor tubes, and rheostat parts.
2. Low porosity bodies, developed principally for use as furnace refractory brick.
3. Vitrified bodies used for exposed electrical devices that are subjected to thermal variations.

Forsterite ($2\text{MgO} \cdot \text{SiO}_2$)

This mixed oxide has high thermal shock resistance but good electrical properties and good mechanical strength. It is somewhat difficult to form and requires grinding to meet close tolerances.

Steatite

Steatites are noted for their excellent electrical properties and low cost. They are easily formed and fired at relatively low temperatures. However, compositions containing little or no clay or plastic material present fabricating problems because of the narrow firing range. Steatite parts are vacuum tight, can be readily bonded to other materials, and can be glazed or ground to high-quality surfaces.

Zircon ($\text{ZrO}_2 \cdot \text{SiO}_2$)

This mixed oxide provides ceramics with strength, low thermal expansion, and relatively high thermal conductivity and thermal endurance. Its high thermal endurance is used to advantage in various porous-type ceramics.

Oxide Coatings

The black oxide finish on steel was one of the most widely used black or blue-black finishes. Some of the advantages of this type of finish are (1) attractive black color; (2) no dimensional changes; (3) corrosion resistance, depending on the final finish dip used; (4) nongalling surface; (5) no flaking, chipping, or peeling because the finish becomes an integral part of the metal surface; (6) lubricating qualities due to its ability to absorb and adsorb the final oil or wax dips; (7) ease and economy of application; and (8) nonelectrolytic solutions and a minimum of plain steel tank equipment required.

The black oxide finish produced on steel is composed essentially of the black oxide of iron (Fe_3O_4) and is considered by many to be a combination of FeO and Fe_2O_3 . It can be produced by several methods: the browning process, carbonia process, heat treatment, and the aqueous alkali-nitrate process. Each of these processes produces a black oxide of iron finish, although the finish produced by each particular process differs in some characteristics. The chemical dip aqueous alkali-nitrate process is the most widely used in applying a black oxide finish on steel.

Aqueous Alkali-Nitrate Process

In this process, a blackening solution is used that is highly alkaline and that also contains strong oxidizing chemicals. Refinements such as penetrants and rectifiers are also used to promote ease of operation, faster blackening, and trouble-free processing. At specific concentrations and boiling temperatures, these solutions will react with the iron in the steel to form the black oxide of iron (Fe_3O_4).

Because the reaction is directly with the iron in the steel, the finish becomes an integral part of the metal itself and, therefore, cannot flake, chip, or peel. For all practical purposes, there are also no dimensional changes. In transforming iron to black iron oxide, it is correct to assume that there is a change in volume. However, because of the highly alkaline nature of the blackening solution and because of the operating temperature, the blackening solution will dissolve a small amount of iron. Therefore, the amount of iron lost in this manner is compensated for by the buildup in volume from the change of iron to iron oxide—resulting in, for all intents and purposes, no dimensional changes. Extremely close measurements have shown that the actual change amounts to a buildup of only about 5 millionths of an inch.

There are types and conditions of steel and many different products that may require special procedures or additional steps.

It is important that only steel or steel alloys be immersed in the solution because other metals such as copper, zinc, cadmium, and aluminum will contaminate it. Many improvements have been incorporated into some proprietary black oxide salts and the latest one will rectify approximately 50 times more contaminants than heretofore. This particular product causes the contaminants to boil to the top, from which they can be skimmed or dragged out and rinsed away during processing.

After a black oxide blackening solution has been mixed, there is a “breaking-in” period that can run from 24 to 48 h, depending on the volume of blackening solution and the amount of work being processed. During this period, if it occurs, erratic blackening may be encountered, resulting in some work being blackened and some remaining partially or totally unblackened.

Chemical black oxide finishes today are being used on a wide variety of consumer and military parts. Some of the most important applications are guns, firearms and components, metal stampings, toys, screws, spark plugs, machine parts, screw machine products, typewriter and calculating machine parts, auto accessories and

parts, tools, gauges, and textile machinery parts. A black oxide finish can normally be used for indoor or semioutdoor applications on metal parts or fabrications that require an economical attractive finish, nominal corrosion resistance, and, in many cases, where *dimensional changes* cannot be tolerated.

Heat Treatment Methods

These methods can be divided into three classes: (1) oven or furnace heating, (2) molten salt bath immersion, and (3) steam heat process.

Oven or Furnace Method

The parts are heated to a temperature of 316°C–371°C at which temperature the metal surface is oxidized to a bluish-black color. The shaded color depends on the temperature and the analyses of the steel.

Molten Salt Bath Method

The oxide finish can be obtained in several ways, depending on the manufacturing or processing requirements:

1. In a molten salt bath composed essentially of nitrate salts maintained at 316°C–371°C, the pieces are first cleaned of any oils, greases, or objectionable oxides and then immersed in the molten bath. They will take on a blue-black finish, after which they are quenched in clean water and given a final oil dip.
2. In a molten nitrate bath in an austempering operation, the pieces are heated to the hardening temperature in a neutral salt hardening bath, after which they are quenched in the molten nitrate bath at 316°C–371°C. They are then removed, cleaned, and given a final oil dip.

Steam Process

In this method, the steel is placed in a retort and heated to a minimum temperature of 316°C. The retort is then purged with steam. Under these conditions, a black oxide is formed on the metal surface.

Browning Process

The browning process is commonly known as a rusting process. The pieces are first thoroughly cleaned and then swabbed with an acidic solution. After drying in a dry atmosphere approximately 77°C, the pieces are then placed in an oven with an atmosphere of 100% humidity and temperature at around 77°C for about 1.5 h. They then become quite rusty and the surface is rubbed down to remove the loose rust.

This procedure is carried out three or four times, after which the surface will have taken on a bluish-black finish. The pieces are then given a final oil dip.

Carbonia Process

To apply a black oxide finish by this method, the pieces are placed in a rotary furnace heated to around 316°C–371°C. Charred bone or other carbonaceous material is placed in the furnace along with a thick oil known as carbonia oil. The floor or cover of the furnace is occasionally opened and closed to allow circulation of air. After the parts have been treated for approximately 4 h, they are removed and then immersed in oil. This finish is essentially a black oxide of iron, but because the metal surface is in contact with carbonaceous material and oil, some black carbon penetrates into the metal surface.

Processes for Nonferrous Metals

The following are typical methods for applying black oxide coatings to nonferrous metals:

1. *Stainless steel*: Aqueous alkali-nitrate and molten dichromate methods. In the aqueous alkali-nitrate method, a solution is made up by using approximately 2.07–2.3 kg of blackening salt mixture to make up a gallon of blackening solution, which is operated at a boiling point of 124°C–127°C. The parts, after cleaning and acid pickling, are immersed in the boiling solution and will take on a black color. They are then given a rust-preventative oil dip. In the molten dichromate method, a molten bath of sodium dichromate or a mixture of sodium and potassium dichromates is used at a molten temperature of 316°C–399°C. The parts are immersed in the molten bath until they take on a blue or blue-black color, after which they are removed and cooled in oil or water. They are then cleaned to remove the salt and oil (is cooled in oil), after which they are given a dip in a clean, rust-preventative oil.
2. *Zinc, zinc plate, zinc-base die castings, and cadmium plate*: Hot molybdate blackening method, chromate and black die method, and the black nickel plate method.
3. *Copper and copper alloys (brasses and bronzes)*: Alkali-chlorite aqueous solution method, cuprammonium carbonate method, anodic oxidation method, and aryl-sulfone monochloramide-sodium hydroxide method.
4. *Aluminum and aluminum alloys*: Anodize and die method.

Oxide Film Replica

A thin film of an oxide of the specimen to be examined. The replica is prepared by air, oxygen, chemical, or electrochemical oxidation of the parent metal and is subsequently freed mechanically or chemically for examination. See also *replica*.

Oxide Rooting

Oxidation penetrating along grain boundaries at and close to the surface of a component.

Oxide Wedging

(1) The buildup of a bulky hard scale in a crack or interface that forces the surfaces apart. The simplest case is where two components are clamped together, and the interface develops a bulky oxide or other solid corrosion product with sufficient volume and compressive strength to force the components apart and perhaps break the bolts or other fasteners. (2) This term is also used to describe the damage observed in welded joints between austenitic and ferritic steels used for some pipework in power plants. Such dissimilar metal joints can develop a wedge-shaped oxide band in the ferritic material immediately adjacent to the weld. However, the damage mechanism in this case is more complicated than a simple jacking action because of (a) carbon diffusion from ferritic to austenitic steels, (b) the complex stress system resulting from the pipe internal pressure and from the expansion differential between ferritic and austenitic materials, and (c) the difference in oxidation characteristics between the austenitic and ferritic steels.

Oxide-Type Inclusions

Oxide compounds occurring as nonmetallic inclusions in metals, usually as a result of deoxidizing additions. In wrought steel products, they may occur as a stringer formation composed of distinct granular or crystalline-appearing particles.

Oxidized Steel Surface

Surface having a thin, tightly adhering oxidize skin (from straw to blue in color), extending inward from the edge of a coil or sheet.

Oxidizing Agent

A compound that causes *oxidation*, thereby itself being reduced.

Oxidizing Atmosphere

A furnace atmosphere with an oversupply of oxygen that tends to oxidize materials placed in it.

Oxidizing Flame

A gas flame produced with excess oxygen in the inner flame that has an oxidizing effect. See also the term *neutral flame*.

Oxyacetylene Welding/Cutting, etc.

Any process of fusion welding, cutting, etc., in which the heat source, at least initially, is provided by combustion of acetylene with oxygen. See *gas cutting* and *powder cutting*.

Oxyfuel Gas Cutting

Any of a group of processes used to sever metals by means of chemical reaction between hot base metal and a fine stream of oxygen. The necessary metal temperature is maintained by gas flames resulting from combustion of a specific fuel gas such as acetylene, hydrogen, natural gas, propane, propylene, or Mapp gas (stabilize methylacetylene–propadiene). See also *oxygen cutting* and the term *cutting torch* (*oxyfuel gas*).

Oxyfuel Gas Spraying

See preferred term *flame spraying*.

Oxyfuel Gas Welding

Any of a group of processes used to fuse metals together by heating them with gas flames resulting from combustion of a specific fuel gas such as acetylene, hydrogen, natural gas, or propane. The process may be used with or without the application of pressure to the joint and with or without adding any filler metal. See the term welding torch (*oxyfuel gas*).

Oxygas Cutting

See preferred term *oxygen cutting*.

Oxygen

An abundant element, constituting about 89% of all water, 33% of the earth's crust, and 21% of the atmosphere. It combines readily with most of the other elements, forming their oxides. It is a colorless and odorless gas and can be produced easily by the electrolysis of water, which produces both oxygen and hydrogen, or by chilling air below -300°F (-184°C), which produces both oxygen and nitrogen. The specific gravity of oxygen is 1.1056. It liquefies at -171°F (-113°C) at 59 atm. *Liquid oxygen* is a pale-blue, transparent, mobile liquid. As gas, oxygen occupies 862 times as much space as the liquid. Oxygen is one of the most useful elements and is marketed in steel cylinders under pressure, although most of the industrial uses are in the form of its compounds. An important direct use is in welding and metal cutting, for which it should be at least 99.5% pure. Oxygen-enriched air is used in a number of oxidation and combustion processes in the steel, cement, glass, petrochemical, refining, and paper-and-pulp industries, and it has potential economic and environmental benefits in waste combustion. Oxygen enrichment improves overall combustion by raising oxygen partial pressure, thus increasing the combustion temperature and waste destruction.

Oxygen is the least refractive of all gases. It is the only gas capable of supporting respiration but is harmful if inhaled pure for a long time. *Ozone* is an allotropic form of oxygen with three atoms of oxygen, O_3 . It is formed in the air by lightning or during the evaporation of water, particularly of spray in the sea. In minute quantities in the air, it is an exhilarant, but pure ozone is an intense poison. It has a peculiar odor, which can be detected with 1 part in 20 million parts of air. Ozone is a powerful oxidizer, capable of breaking down most organic compounds and bleaching vegetable colors. Its use as an alternative to chlorine for treating water and wastewater has risen in recent years because it is a safer and stronger oxidizing agent. *Liquid ozone* explodes violently in contrast with almost any organic substance. It is bright blue and is not attracted by magnet, although liquid oxygen is attracted. Ozone absorbs ultraviolet rays, and a normal blanket in the upper ozonosphere at heights of 60,000–140,000 ft (18,288–42,672 m), with 1 part per 100,000 parts of air, shields the earth from excess shortwave radiation from the sun. The destruction of the stratospheric ozone layer is resulting in the cutting back in usage of chlorofluorocarbons and other inert chlorinated compounds. At ground levels, however, ozone concentrations are rising due to increased use of fossil fuels; such higher ozone levels are viewed as deleterious to health. As an oxidizer in the rubber industry, ozone is known as *activated oxygen*. It is used widely as a catalyst in chemical reactions. It is made commercially by bombardment of oxygen with high-speed electrons.

Oxygen Arc Cutting

An oxygen cutting process used to sever metals by means of the chemical reaction of oxygen with the base metal at elevated temperatures. The necessary temperature is maintained by an arc between a consumable tubular electrode and the base metal. See *gas cutting*, *powder cutting*, and also *thermic lance*.

Oxygen Concentration Cell

See *differential aeration cell*.

Oxygen Cutting

Metal cutting by directing a fine stream of oxygen against a hot metal. The chemical reaction between oxygen and the base metal furnishes heat for localized melting, hence cutting. In the case of

O

oxidation-resistant metals, the reaction is facilitated by the use of a chemical flux or metal powder. See also *metal powder cutting*.

Oxygen Deficiency

A form of *crevice corrosion* in which galvanic corrosion proceeds because oxygen is prevented from diffusing into the crevice.

Oxygen Gouging

Oxygen cutting in which a bevel or groove is formed.

Oxygen Grooving

See preferred term *oxygen gouging*.

Oxygen Lance

A length of pipe used to convey oxygen either beneath or on top of the melt in a steelmaking furnace or to the point of cutting in *oxygen lance cutting*. See also the terms *argon oxygen decarburization* and *basic oxygen furnace*.

Oxygen Lance Cutting

An oxygen cutting process used to sever metals with oxygen supplied through a consumable lance; the preheat to start the cutting is obtained by other means.

Oxygen Lance/Blown Processes

Various processes for producing refined steel from pig iron and/or scrap, in which the molten metal is exposed to oxygen injected from beneath, as in the Bessemer process or is delivered from above by a water-cooled tube, that is, a lance.

Oxygen Probe

An atmosphere-monitoring device that electronically measures the difference between the partial pressure of oxygen in a furnace or furnace supply atmosphere and the external air.

Oxygen-Free Copper

Electrolytic copper free from cuprous oxide, produced without the use of residual metallic or metalloidal deoxidizers.

Oxyhydrogen Cutting

An *oxyfuel gas cutting* process in which the fuel gas is hydrogen.

Oxyhydrogen Welding

An *oxyfuel gas welding* process in which the fuel gas is hydrogen.

Oxynatural Gas Cutting

An *oxyfuel gas cutting* process in which the fuel gas is natural gas.

Oxypropane Welding

An *oxyfuel gas welding* process in which the fuel gas is propane.

Ozone

A powerfully oxidizing allotropic form of the element oxygen. Both liquid and solid ozones are opaque blue-black in color, similar to that of ink. See *oxygen*.

Ozone Test

Exposure of material to a high concentration of ozone to give an accelerated indication of degradation expected in normal environments.

“p”-Type Semiconductor

See *semiconductor*.

PA

See *polyamides*.

Pack Carburizing

A method of surface hardening of steel in which parts are packed in a steel box with a carburizing compound and heated to elevated temperatures. Common carburizing compounds contain 8%–10% alkali or alkaline earth metal carbonates (e.g., barium carbonate, BaCO_3) bound to hardwood charcoal or to coke by oil, tar, or molasses. This process has been largely supplanted by gas and liquid carburizing processes. See *case hardening*.

Pack Nitriding

A method of surface hardening of steel in which parts are packed in a steel box with a nitriding compound and heated to elevated temperatures.

Package (Composites)

Yarn, roving, and so forth for reinforcing plastics in the form of units capable of being unwound and suitable for handling, storing, shipping, and use.

Package (Electronics)

In the electronics/microelectronics industry, an enclosure for a single element, and integrated circuit, or a hybrid circuit.

Packed Density

See preferred term *tap density*.

Packed Rolling

Hot rolling a pack of two or more sheets of metal; scalar prevents their being welded together. Unlike cladding, there is no intention that the sheets will bond to each other, this being inhibited by oxide or oil films.

Packing Density

See preferred term *apparent density*.

Packing Material

Any material in which powder-metallurgy compacts are embedded during the presintering or sintering operation. The material

may act as a getter to protect the compacts from contamination. See also *getter*.

Pad

The general term used for that part of a die that delivers holding pressure to the metal being worked.

Pad Lubrication

A system of lubrication in which the lubricant is delivered to a bearing surface by a pattern of felt or similar material.

Padding

In foundry practice, the process of adding metal to the cross section of a casting wall, usually extending from a riser, to ensure adequate feed metal to a localized area during solidification where a shrink would occur if the added metal were not present.

Paddle Mixer

A mixture that uses paddles mounted on a rotating shaft or disk to move and mix the metal powder.

PAEK

See *polyaryletherketone*.

PAI

See *polyamide-imide*.

Paint

Paint is a term used since the dawn of history to designate cosmetics, marking chalks and pastes, tempera plaster, and colored fluids applied to surfaces for artistic, decorative, or weatherproofing purposes. The term survives today as a general marketing designation for decorative and protective formulations used in architectural, commercial, and industrial applications, with such diverse materials as lacquer, varnish, baking finishes, and specialty coating systems covered in a single category.

There is a general definition that suits most products: paint is a fluid, with viscosity, drying time, and flowing properties dictated by formulation, normally consisting of a vehicle or binder, a pigment, a solvent or thinner, and a drier, which may be applied in relatively thin layers and which changes to a solid in time. The change to a solid may or may not be reversible and may occur by evaporation of the solvent, by chemical reaction, or by a combination of the two.

Paint is a general name sometimes used broadly to refer to all types of organic coatings. However, by definition, paint refers to a solution of a pigment in water, oil, or organic solvent, used to cover wood or metal articles either for protection or for appearance.

P

Solutions of gums or resins, known as varnishes, are not paints although their application is usually termed painting. Enamels and lacquers, in the general sense, are under the classification of paints, but specifically the true paints do not contain gums or resins. Stain is a varnish containing enough pigment or dye to alter the appearance or tone of wood in imitation of another wood or to equalize the color in wood. It is usually a dye rather than a paint.

In modern technology, paint is classified in three major categories because of differing performance requirements: architectural paints, commercial finishes, and industrial coatings. A fourth category, artistic media, now admits inks, cements, pastes, dyes, plastics, semisolids, and conventional pigmented oils as acceptable materials.

Architectural Paints

These are air-drying materials applied by brush or spray to architectural and structural surfaces and forms for decorative and protective purposes. Materials are classified by formulation type as solvent thinned and water thinned.

Solvent-Thinned Paints

The drying mechanism of solvent-thinned paints predominantly may be by solvent evaporation, oxidation, or a combination of the two, and paints in this classification are subdivided accordingly.

Solvent-thinned paints that dry essentially by solvent evaporation rely on a fairly hard resin as the vehicle. Resins include shellac, cellulose derivatives, acrylic resins, vinyl resins, and bitumens. Shellac is usually dissolved in alcohol and is commonly used as shellac varnish. Paints based on nitrocellulose or other cellulose derivatives are usually called lacquers. Paints derived from acrylic and vinyl resins usually require a solvent such as ketone, and their architectural applications are limited. However, in addition to the formulation of agents that result in emulsion, polymerization has produced products with extensive architectural use. Bitumens or asphalts of petroleum or coal-tar derivation are most often used in roofing, and waterproofing applications where heavy layers are required an opportunity for renewal may be limited.

In paints that dry by oxidation, the vehicle is usually an oil or an oil-based varnish. These usually contain driers to accelerate drying of the oil. Paints based essentially on linseed oil with suitable pigments such as titanium dioxide and zinc oxide extenders once were the conventional exterior house paints. However, the successful development of polyvinyl acetate and acrylic emulsion types of paint reached the point where these materials became dominant in the exterior house paint market.

Water-Thinned Paints

This group of paints may be subdivided into those in which the vehicle is dissolved in water and those in which it is dispersed in emulsion form.

Paints with water-soluble vehicles include the calcimines, in which the vehicle is glue, and casein paints, in which the vehicle is casein or soybean protein. These paints are water sensitive and have only limited use. Synthetic resins soluble to water and treatments rendering drying oils soluble in water are relatively recent developments. Water evaporates from paints having these materials in their formulation, and further chemical change, either oxidation or heat polymerization, converts the vehicle so that the film no longer is water sensitive. These paints have a limited market because of the widespread utilization of latex emulsions.

Nearly any solvent-thinned paint may be emulsified by the addition of a suitable emulsifier and adequate agitation. The use of

fugitive emulsifiers and of vehicles especially processed for use in emulsion paints has produced materials with excellent water resistance, color retention, and durability when cured. Materials formed by emulsion polymerization are described as a latex, and products are called latex paints. The most common latexes are made from a copolymer of butadiene and styrene, from polyvinyl acetate, and from acrylic resin. Properties and performance differ slightly among these paints, but as a group, they dominate the architectural market.

Enamel Paints

Enamel paint is an intimate dispersion of pigments in either a varnish or a resin vehicle or in a combination of both. Enamels may dry by oxidation at room temperature and/or by polymerization at room or elevated temperatures. They vary widely in composition, in color and appearance, and in properties. Although they generally give a high-gloss finish, some give a semigloss or eggshell finish, and still others give a flat finish. Enamels as a class are hard and tough and offer good mar and abrasion resistance. They can be formulated to resist attack by the most commonly encountered chemical agents in corrosive atmospheres and have good weathering characteristics.

Because of their wide range of useful properties, enamels are probably the most widely used organic coating in industry. One of their largest areas of use is as coatings for household appliances—washing machines, stoves, kitchen cabinets, and the like. A large proportion of refrigerators, for example, are finished with synthetic baked enamels. These appliance enamels are usually white and therefore must have a high degree of color and gloss retention when subjected to light and heat. Other products finished with enamels include automotive products; railway, office, sports, and industrial equipment; toys; and novelties.

House Paints

House paint for outside work consists of high-grade pigment and linseed oil, with a small percentage of a thinner and drier. The volatile thinner in paints is for ease of application, the drying oil determines the character of the film, the drier is to speed the drying rate, and the pigment gives color and hiding power. Part or all of the oil may be replaced by a synthetic resin. Many of the newer house paints are water-based paints.

Paints are marketed in many grades, some containing pigments extended with silica, talc, barytes, gypsum, or other material, fish oil or inferior semidrying oils in place of linseed oil, and mineral oils in place of turpentine. Metal paints contain basic pigments such as red lead, ground in linseed oil, and should not contain sulfur compounds. Red lead is a rust inhibitor and is a good primer paint for iron and steel, although it is now largely replaced by chromate primers. White lead has a plasticizing affect that increases adhesion. It is stable and not subject to flaking. Between some pigments and the vehicle, there is a reaction that results in progressive hardening of the film with consequent flaking or chalking, or there may be a development of water-soluble compounds. Linseed oil reacts with some basic pigments, giving chalking and flaking. Fading of a paint is usually from chalking. The composition of paints is based on relative volumes because the weights of pigments vary greatly, although the custom is to specify pounds of dry pigment per gallon of oil.

Bituminous Paints

Bituminous paints are usually coal tar or asphalt in mineral spirits, used for the protection of piping and tanks and for waterproofing concrete. For line pipe, heavy pitch coatings are applied hot, but a bitumen primer is first applied cold. The bituminous paints also have poor solvent resistance.

Commercial Finishes

These include air-drying or baking-cured materials applied by brush, spray, or magnetic agglomeration to kitchen and laundry appliances, automobile, machinery, and furniture and are used in highway marking materials. Paints in this group are subdivided by their drying mechanism.

Air-Drying Finishes

These materials once were the conventional factory-applied finishes. In the finishing of furniture, lacquers, varnishes, and shellac are still extensively used, but epoxy and unsaturated polyester materials have been adopted in recent years. Automobile manufacturers used in lacquers in air-drying alkyd enamels until the adoption of baked acrylic and urea finishes. Epoxy, urethane, and polyester resins, converted at room temperature with a suitable catalyst, are beginning to replace conventional solvent-thinned paints as machinery finishes. The marking of center lines on highways and other painted areas for the control of traffic requires a finish that dries rapidly, adheres well to both asphalt and concrete, and resists abrasion and staining. Solvent-thinned materials especially formulated for this service from alkyds, modified rubbers, and other resins are now extensively used, but some latex formulations have been tried with success.

Baking Finishes

Urea and melamine resins polymerize by heat and are used in baking finishes where extreme hardness, chemical resistance, and color retention are required as on kitchen and laundry appliances. Baked acrylic resin formulations now dominate the automobile finish market. Certain phenolic resins are converted by heat to produce finishes with excellent water and chemical resistance.

Industrial Coatings

Industrial coatings are subdivided by their intended service: corrosion-resistant coatings, high-temperature coatings, and coatings for immersion service. Materials in each subdivision are applied in a system that usually requires a base coat or primer, and intermediate coat or coats, and a top or finish coat.

Corrosion-Resistant Coatings

These are materials generally inert when cured to deterioration by acidic, alkaline, or other corrosive substances and applied in a system as a protective layer over steel or other substrates susceptible to corrosion attack.

The base, or prime, coat in the corrosion-resistant system is applied to dry surfaces prepared by abrasive blasting or other methods to a specified degree of cleanliness and toughness. The prime coat provides adhesion to the substrate for the entire coating system: adherence is by mechanical anchorage, chemical reaction, or a combination of the two. Prime coat materials once were predominantly a red lead pigment dispersed in linseed oil and cured by oxidation. Today, the prime coat material, commonly specified for application to steel surfaces is a dispersion of zinc in a suitable inorganic or organic vehicle. Although these zinc-rich primers now dominate the market where protection of steel is concerned, prime coat materials generically similar to subsequent coats in the system are specified when protection of nonferrous or nonmetallic substrates from corrosion attack is required.

An intermediate coat in the corrosion-resistant system is not always required. When used, intermediate coat materials usually are high-build layers of the same generic type specified for the top or surface coat and are applied only to increase the dry-film thickness of the protective area in places where airborne corrosive fumes,

particulates, or droplets are heavily concentrated or where splash and spillage of corrosive fluids are relatively frequent.

A top or surface coat in the corrosion-resistant system may be selected from a variety of formulations with vehicles that include phenolic resins, chlorinated rubber, coal tar and epoxy combination, epoxy resin cured from a solvent solution with polyfunctional amines, polyamide resins, vinyl resin in solvent solution, elastomers, polyesters, and polyurethanes.

Top coat materials are required to have good scaling properties; high resistance to corrosive deterioration, oxidation, erosion, and ultraviolet degradation; and relative freedom, when cured, from pinholes, blisters, and crevices. Color retention is a desirable but not a mandatory requirement.

Selection of materials able to withstand corrosive attack in a given environment and to maintain cohesion and integrity among the various coats in system has become a technological specialty.

High-Temperature Coatings

These are materials used to alleviate or prevent corrosion, thermal shock, fatigue, oxide sublimation, and embrittlement of metals at high temperature.

Formulation of high-temperature coatings is a relatively recent development in the art. Material problems encountered since World War II such as high-temperature chemical reactions, production of steel by the oxygen lance process, aerodynamic heating to complex high-speed aircraft, and aerospace vehicle launching and reentry have been alleviated to an extensive degree by the results of research toward finding high-strength resistant metals and cements and toward producing coatings serviceable at high temperatures. Research continues as higher and higher temperatures are required by technological developments and radiation effects in outer space are better understood.

Available high-temperature coatings include inorganic zinc dispersed in a suitable vehicle, serviceable to 400°C; a phosphate bonding system in which ceramic fillers are mixed with an aqueous solution of monoaluminum phosphate, applied by spraying, brushing, or dipping, and serviceable to 1538°C after curing at 204°C; and a "ceramic gold" coating used on jet engine shrouds and having a temperature limit near 538°C.

Ablative formulations that absorb heat through melting, sublimation decomposition, and vaporization, or that expand upon heating to form a foamlike insulation that replenishes itself until the coating is depleted, employ silicone rubber or silicone resins or polyamide and tetrafluoroethylene polymers to provide short-term heat protection from 147°C to 538°C.

Coatings for Immersion Service

Included here are materials used to coat or line interior surfaces of vessels of containers holding or storing corrosive fluids, pipelines to which corrosive fluids are the flowing medium, and hoppers or bins conveying or holding abrasive or corrosive pellets or particulates.

These coatings are usually applied in relatively high-build systems to carefully cleaned and prepared surfaces. Air-drying formulations are used when extensive coverage is required and where polymerization by automatic heating apparatus is impractical. Small vessels, pipe spools, and assembly components may be protected by coatings cured by oven baking.

Coatings for immersion service may be selected from a variety of formulations that include asphalt, chemically cured coal tar, thermoplastic coal tar, epoxy-furans, amine-cured epoxies, fluorocarbons, furfuryl alcohol resins, neoprene, baked unmodified phenolics, unsaturated polyesters, polyether resins, low-density polyethylene,

P

chlorosulfonated polyethylene, polyvinyl chloride plastisols, resinous cements, rubber, and urethanes, among other vehicles.

Selection and specification of coatings for immersion service has become a technological specialty.

Paint Removers

Paint removers, for removing old paint from surfaces before refinishing, are either strong chemical solvents or strong caustic solutions. In general, the more effective they are in removing the paint quickly, the more damaging they are likely to be to the wood or other organic material base. The hiding power of a paint is measured by the quantity that must be applied to a given area of a black and white background to obtain nearly uniform complete hiding. The hiding power is largely in the pigment, but when some fillers of practically no hiding power alone, such as silica, are ground to microfine-particle size, they may increase the hiding power greatly. Paint making is a highly developed art, and the variables are so many, and the possibilities for altering the characteristics by slight changes in the combinations are so great that the procurement specifications for paints are usually by usage requirements rather than by composition.

Palladium

Palladium (symbol Pd), a rare metal, is found in the ores of platinum. It resembles platinum, but is slightly harder and lighter in weight and has a more beautiful silvery luster. It is only half as plentiful but is less costly. The specific gravity is 12.10 and a melting point is 1552°C. Annealed, the metal has a hardness of Brinell 40 and a tensile strength of 186 MPa.

It is highly resistant to corrosion and to attack by acids, but, like gold, it is dissolved in aqua regia. It alloys readily with gold and is used in some white golds. It alloys in all proportions with platinum and the alloys are harder than either constituent.

Physical and Chemical Properties

Palladium is soft and ductile and can be fabricated into wire and sheet. The metal forms ductile alloys with a broad range of elements. Palladium is not tarnished by dry or moist air at ordinary temperatures. At temperatures from 350°C to 790°C, a thin protective oxide forms in air, but at temperatures from 790°C, this film decomposes by oxygen loss, leaving the bright metal. In the presence of industrial sulfur-containing gases, a slight brownish tarnish develops; however, the alloying palladium with small amounts of iridium or rhodium prevents this action.

At room temperature, palladium is resistant to nonoxidizing acids such as sulfuric acid, hydrochloric acid, hydrofluoric acid, and acetic acid, but the metal is attacked by nitric acid. Palladium is also attacked by moist chlorine and bromine.

In its pure form, it is malleable and corrosion resistant although it oxidizes in air above about 400°C. It can absorb about 1000 times its own volume of hydrogen at atmospheric pressure, and it is readily permeated by the gas above about 300°C, so it is used as a filter, typically in fine tube form, to purify hydrogen. It is used for jewelry in its pure form or for larger items alloyed with about 3% of either ruthenium or molybdenum. With about 25% copper, 5% nickel, and 1% nickel, it forms palladium copper that has good machining characteristics, reasonable hardness, and excellent corrosion resistance. With 50% gold, it forms palladium gold used as a dental material.

Uses

The major applications of palladium are in the electronics industry, where it is used as an alloy with silver for electrical contacts

or in pastes in miniature solid-state devices and in integrated circuits. Palladium is widely used in dentistry as a substitute for gold. Other consumer applications are in automobile exhaust catalysts and jewelry.

The palladium–silver–gold alloys offer a series of noble brazing materials covering a wide range of melting temperatures. A palladium–silver alloy can be used as a diffusion septum for the separation of hydrogen from gas mixtures.

Palladium supported on carbon or alumina is used as a catalyst for hydrogenation and dehydrogenation in both liquid- and gas-phase reactions. Palladium finds widespread use in catalysis because it is frequently very active under ambient conditions and it can yield very high selectivities. Palladium catalyzes the reaction of hydrogen with oxygen to give water. Palladium also catalyzes isomerization and fragmentation reactions.

Palladium alloys are also used for instrument parts and wires, dental plates, and Felton-10 nibs. Palladium is valued for electroplating because it has a fine white color that is resistant to tarnishing even in sulfur atmospheres.

Although palladium has low electric conductivity, 16% that of copper, it is valued for its resistance to oxidation and corrosion. Palladium-rich alloys are widely used for low-voltage electric contacts. Palladium–silver alloys, with 30%–50% silver, for relay contacts, have 3%–5% the conductivity of copper. A palladium–silver alloy with 25% silver is used as a catalyst in powder or wire-mesh form. A palladium–copper alloy for sliding contacts has 40% copper with a conductivity of 5% that of copper. Many of the palladium salts, such as sodium palladium chloride, are easily reduced to the metal by hydrogen or carbon monoxide and are used in coatings and electroplating.

Palladium leaf is palladium beaten into extremely thin foil and used for ornamental work like gold leaf. Hydrogen forms solid solutions with palladium, forming *palladium sponge*, which is used for gas lighters. Palladium powder is made by chemical reduction and has a purity of 99.9% with amorphous particles 12–138 μ in (0.3–3.5 μ m) in diameter. Atomized powder has spherical particles of 50–200 mesh and is free flowing. The powders are used for coatings and parts for service temperatures to 2300°F (1260°C). *Palladium flake* has tiny laminar platelets with average diameter of 118 μ in. (3 μ m) and thickness of 3.9 μ in. (0.1 μ m). The particles form an overlapping film in coatings. For autocatalytic converters, a “palladium-only” catalyst developed by Allied Signal can reduce precious metal caused by excluding platinum and rhodium.

Palm Oil

An oil obtained from the fleshy covering of the seed nuts of several species of palm trees, native to tropical Africa, but also grown in Central America. The oil is used as a fluxing dip in the manufacture of tinplate; for soaps, candles, and margarine; and for the production of palmitic acid. About 10% weight of the palm oil is recovered as by-product glycerin in making soaps or in producing the acid.

Palm oil contains 50%–70% palmitic acid, which in the form of glyceride is an ingredient of many fats. When isolated, it is a white crystalline powder of specific gravity 0.866 and melting point 65°C, soluble in hot water. It is used for soaps, cosmetics, pharmaceuticals, and food emulsifiers and in making plastics. *Greco 55L*, which is a white crystalline solid, for cosmetics and soaps, is 50% palmitic acid with the balance stearic acid.

The oil from the kernel of the palm nut, known as *palm kernel oil*, has different characteristics from palm oil. It contains about 50% lauric acid, 15% myristic acid, 16% oleic acid, and 7% palmitic acid, together with capric and caprylic acids found in coconut oil, while

palm oil is very high in palmitic and oleic acids. The specific gravity is 0.873, iodine number 16–23, saponification value 244–255, and melting point 75°F–86°F (24°C–30°C).

PAN

See *polyacrylonitrile*.

Pancake Forging

A rough forged shape, usually flat, which can be obtained quickly with minimal tooling. Considerable machining is usually required to attain the finish size.

Pancake Grain Structure

A metallic structure in which the lengths and widths of individual grains are large compared to their thicknesses.

Paper

Paper is a flexible web or mat of fibers isolated from wood or other plant materials by the operation of pulping. Nonwovens are webs or mats made from synthetic polymers, such as high-strength polyethylene fibers, that substitute for paper in large envelopes and tote bags.

Paper is made with additives to control the process and modify the properties of the final product. The fibers may be whitened by bleaching, and the fibers are prepared for papermaking by the process of refining. Stock preparation involves removal of dirt from the fiber slurry and mixing of various additives to the pulp prior to papermaking. Papermaking is accomplished by applying a dilute slurry of fibers in water to a continuous wire or screen; the rest of the machine removes water from the fiber mat. The steps can be demonstrated by laboratory handsheet making, which is used for process control.

Although there is no distinct line to be drawn between papers and paperboard, paper is usually considered to be less than 0.15 mm thick. Most all fiber sheets over 0.30 mm thick are considered to be board. In the borderline range of 0.15–0.30 mm, most are considered to be papers, although some are classified as board.

Although paper has numerous specialized uses in products as diverse as cigarettes, capacitors, and countertops (resin-impregnated laminates), it is principally used in packaging (~50%), printing (~40%), and sanitary (~7%) applications. Paper was manufactured entirely by hand before the development of the continuous paper machine; this development allowed the U.S. production of paper to increase by a factor of 10 during the nineteenth century and by another factor of 50 during the twentieth century. In 1960, the global production of paper was 70 million tons (50% by the United States); in 1990, it was 210 million tons (30% by the United States). The annual per capita paper use in the United States is 300 kg, and about 40% is recovered for reuse.

Material of basis weight greater than 200 g/m² is classified as paperboard; lighter material is called paper. Production by weight is about equal for these two classes. Paperboard is used in corrugated boxes; corrugated material consists of top and bottom layers of paperboard called linerboard, separated by fluted corrugating paper. Paperboard also includes chipboard (a salad material used in many cold-cereal boxes, shoeboxes, and the backs of paper tablets) and food containers.

Mechanical pulp is used in newsprint, catalog, and other short-lived papers; they are only moderately white and yellow quickly with

age because the lignin is not removed. A mild bleaching treatment (called brightening) with hydrogen peroxide or sodium dithionite (or both) masks some of the color of the lignin without lignin removal. Paper made with mechanical pulp and coated with clay to improve brightness and gloss is used in 70% of magazines and catalogs, and in some enamel grades. Bleach chemical pulps are used in higher grades of printing paper used for xerography, typing paper, tablets, and envelopes; these papers are termed uncoated wood-free (meaning free of mechanical pulp). Coated wood-free papers are of high to very high grade and are used in applications such as high-quality magazines and annual reports; they are coated with calcium carbonate, clay, or titanium dioxide.

Like wood, paper is a hygroscopic material; that is, it absorbs water from, and also releases water into, the air. It has an equilibrium moisture content of about 7%–9% at room temperature and 50% relative humidity. In low humidities, paper is brittle; in high humidities, it has poor strength properties.

General Features and Uses

The major attribute of paper is its extreme versatility. A wide range of end properties can be obtained by control of the variables in (1) original selection of the type and size of fiber, (2) the various pulp processing methods, (3) the actual web-forming operation, and (4) the treatments that can be applied after the paper has been produced.

Papers have been specifically developed for a number of engineered applications. These include gasketing; electrical, thermal, acoustical, and vibration insulation; liquid and air filtration; composite structural assemblies; simulated leathers and backing materials; cord or twine; and as yarns for paper and textiles.

Wood

Wood, a diverse, variable material, is the source of about 90% of the plant fiber used globally to make paper. Straw, grasses, canes, bast, seed hairs, and reeds are used to make pulp, and in many regards, their pulp is similar to wood pulp. Fibers are tubular elements of plants and contain cellulose as the principal constituent. Softwoods (gymnosperms) have fibers that are about 3–5 mm long, while in hardwoods (angiosperms), they are about 0.8–1.6 mm long. In both cases, the length is typically about 100 times the width. Softwoods are used in papers such as linerboard where strength is the principal intent. Hardwoods are used in papers such as tissue and printing to contribute to smoothness. Many papers also include some softwood pulp for strength and some hardwood pulp for smoothness.

Wood consists of three major components: cellulose, hemicellulose, and lignin. The first two are white polysaccharides of high molecular weight that are desirable in paper. Cotton is over 98% cellulose, while wood is about 45%. Hemicellulose, although not water soluble, is similar to starch. The hydroxyl groups of these materials allow fibers to be held together in paper by hydrogen bonding. Adhesives are not required to form paper, but some starch is usually used and has a similar effect to the hemicelluloses in helping the fibers bond together. Lignin makes up about 25%–35% of softwoods and 18%–25% of hardwoods. It is concentrated between fibers.

Paper Production

Most papers are made from crude fibrous wood pulps.

Types of Pulp

The type of pulp to a large extent determines the type of paper produced. Pulps are generally classified as mechanical or chemical wood pulps.

P

Mechanical wood pulps produced by mechanical processes include

1. Ground wood, which is used in a number of papers where absorbency, bulk, opacity, and compressibility are primary requirements and permanence and strength are secondary
2. Defibrated pulps, which are used for insulating board, hardboard, or roofing felts where good felting properties are required
3. Exploded pulps, used for building and insulation hardboards, or so-called wood composition materials

Chemical wood pulps are produced by “cooking” the fibrous material and various chemicals to provide certain characteristics. They include the following:

1. Sulfite pulps, used in the bleached or unbleached state for papers ranging from very soft or weak to strong grades. There are about 12 grades of sulfite pulps.
2. Neutral sulfite or monosulfite pulps, used for strong papers for bags, wrappings, and envelopes.
3. Sulfate or kraft pulps, providing high strength, fair cleanliness, and, in some instances, high absorbency. Such pulps are used for strong grades of unbleached, semibleached, or bleached paper (called kraft paper) and board.
4. Soda pulps, used principally in combination with bleached sulfite or bleached sulfate pulp for book-printing papers.
5. Semichemical pulps, used for specialty boards, corrugating papers, glassine and greaseproof papers, test liners, and insulating boards and wallboards.
6. Screenings, used principally for coarse grades of paper and board, such as mill wrapper, and as a substitute for chipboard, corrugated papers, and insulation board.

Papermaking

The two basic types of papermaking machines are the Fourdrinier and the cylinder machines; the Fourdrinier machine is the most commonly used.

In Fourdrinier papermaking, the pulp, mixed to a consistency of 97.5%–99.5% water, is fed continuously to Fourdrinier, which consists of an endless belt of fine-mesh screen called the “wire.”

As the pulp web travels along the wire, water drains from it into suction boxes. As it leaves the wire (at about 83% water), it passes through presses, and usually a variety of other types of equipment, such as dryers and calender rolls, depending on the type of paper produced.

Cylinder machine papermaking differs from Fourdrinier in that the web of pulp is formed on a cylindrical mold surface instead of a continuous wire covered with fine-wire cloth, which revolves in a vat of paper stock or pulp. The felt conveyor carries the resulting web to the press and dryers.

The cylinder machine is used to produce a greater variety of paper thicknesses, ranging from the thinnest tissue to the thickest building board.

Bleaching

Chemical pulp for printing paper has 3%–6% lignin, which gives the pulp a brown color. This lignin is removed with bleaching chemicals and in 4–8 stages. Each stage consists of a pump to mix the bleaching agent with the pulp, a retention tower to allow the chemical to react with the pulp for 30 min to several hours, and a washing unit to

remove the solubilized lignin and residual chemicals from the pulp. Usually an oxidizing material is followed by a stage of alkali extraction, because lignin becomes more soluble at high pH. A common bleaching sequence involves elemental chlorine, alkali extraction, and, finally, chlorine dioxide. Sodium hypochlorite, also found in household liquid bleach, is sometimes used. There is some pressure for the bleaching process to be elemental chlorine-free. This is possible by using oxygen as the first bleaching chemical, chlorine dioxide in place of chlorine, and hydrogen peroxide as a bleaching agent.

Types of Paper

In the broadest classification, there are three basic types of papers: cellulose fiber, inorganic fiber, and synthetic organic fiber papers.

Cellulose Fiber Papers

These papers, made from wood pulp, constitute by far the largest number of papers produced. A great many of the engineering papers are produced from kraft or sulfate pulps. The term *kraft* is used broadly today for all types of sulfate papers, although it is primarily descriptive of the basic grades of unbleached sulfate papers, where strength is the chief factor and cleanliness and color are secondary. By various treatments, kraft can be altered to produce various grades of condenser, insulating, and sheathing papers.

Other types of vegetable fibers used to produce papers include

1. Rope, used for strong, pliable papers, such as those required in cable insulation, gasketing, bags, abrasive papers, and pattern papers
2. Jute, used for papers possessing excellent strength and durability
3. Bagasse, used for paper for wallboard and insulation, usually where strength is not a primary requirement
4. Esparto, used for high-grade book or printing papers (A number of other types of pulps are also used for these papers.)

Inorganic Fiber Papers

There are three major types of papers made from inorganic fibers:

1. Asbestos is the most widely used inorganic fiber for papers. Asbestos papers are nonflammable and resistant to elevated temperatures and have good thermal insulating characteristics. They are available with or without binders and can be used for electrical insulation or for high-temperature reinforced plastics.
2. Fibrous glass can be used to produce porous and nonhydrating papers. Such papers are used for filtration and thermal and electrical insulation and are available with or without binders. High-purity silica glass papers are also available for high-temperature applications.
3. Ceramic fiber (aluminum silicate) papers provide good resistance to high temperatures and low thermal conductivity, have good dielectric properties, and can be produced with good filtering characteristics.

Synthetic Organic Fiber Papers

A great deal of research has been carried out on the use of such synthetic textile fibers as nylon, polyester, and acrylic fibers in papers. Some of the earliest appear highly promising for electrical insulating uses. Others appear promising for chemical or mechanical applications. They are most commonly combined with other fibers in a paper, primarily to add strength.

Paper Treatments

Papers can be impregnated or saturated, coated, laminated, or mechanically treated. The major treatments used are covered and indicate the extent of treatments available.

Impregnation or Saturation

Impregnation or saturation can be carried out either at the beater stage in the processing of the pulp or after the paper web has been formed. Beater saturation permits saturation of nonporous or adsorbent papers, whereas paper saturated after manufacture must be of the absorbent type to permit complete impregnation by the saturant.

Papers can be saturated or impregnated with almost any known resin or binder. Probably the most commonly used are asphalt for moisture resistance; waxes for moisture vapor and water resistance; phenolic resins for strength and rigidity; melamine and certain ureas for wet strength (not to be confused with moisture resistance); rubber latexes, both natural and synthetic, for resilience, flexibility, strength, and moisture resistance; epoxy or silicone resins for dielectric characteristics at elevated temperatures; and ammonium salts, or other materials, for flame proofing.

A number of proprietary beater-saturated papers are currently available. They are used primarily for gasketing, filtration, simulated leathers, and backing materials. Most of these consist of cellulose or asbestos fibers blended with natural or synthetic rubbers. In some cases, cork is added to the blend for increase compressibility. Another type of proprietary beater-saturated paper consists of leather fibers blended with rubber latexes.

Coatings

Papers may be coated either by the paper manufacturer or by converters. Coating materials, which also impregnate the paper to a greater or lesser degree, include practically every known resin or binder and pigment used in the paint industry. Coatings can be applied in solvent or water solutions, water emulsions, hot melts, and extrusion coatings or in the form of plastisols or organosols.

The most important properties provided by coatings are (1) gas and water vapor resistance; (2) water, liquid, and grease resistance; (3) flexibility; (4) heat sealability; (5) chemical resistance; (6) scuff resistance; (7) dielectric properties; (8) structural strength; (9) mold resistance; (10) avoidance of fiber contamination; and (11) protection of printing.

Coating materials range from the older asphalts, waxes, starches, casein, shellac, and natural gums to the newer polyethylenes, vinyl copolymers, acrylics, polystyrenes, alkyds, polyamides, cellulotics, and natural or synthetic rubbers.

Laminations

Paper can be laminated to other papers or to other films to provide a variety of composite structures.

Probably, the most common types of paper laminates are those composed of layers of paper laminated with asphalt to provide moisture resistance and strength. Simple laminations of paper can be so oriented that overall characteristics of the composite are isotropic.

Laminating paper with plastics or other types of films or with metal foils will, in many cases, combine the desirable properties of the film or foil with those of the paper.

Scrim is a mat of fibers, usually laminated as a "core" material between two faces of paper. It is usually used to provide strength but can also provide bulk for cushioning, or a degree of "hand" to the composite material.

Mechanical Treatments

Several mechanical treatments can be applied to papers to provide particular special properties.

Crimping, which can be done either on the paper web or on the individual fibers of the paper, essentially adds stretch or extensibility. Crimping the paper web results in crepe paper with improved strength, stretch, bulk, and conformability and with texture similar to that of cloth. The creping process usually consists of "crowding" the paper into small pleats or folds with a "doctor." Typical range of elongation or stretch obtainable is 20%–300%. Cross-creping can provide controllable stretch in directions perpendicular to each other, further improving drapability.

A high degree of stretch, conformability, and flexibility is produced by a patented process that differs from creping in that the individual fibers in the paper web are crimped, rather than the web itself. The amount of stretch is variable, but about 10% stretch in the machine direction seems to be optimal for most industrial applications. The major advantages of this type of paper are reported to be a high degree of toughness, combined with a smooth surface, and a high resistance to tearing or punching.

Twisting

Twisting is used to convert paper to twine or yarns. Such yarns have substantially higher strength than the paper from which they are made.

Twisting papers are usually sulfate papers, either bleached or unbleached. High tensile strength is required in the machine direction, and the heavier-weight papers should usually be soft and pliable. Treatments to impart such characteristics as wear and moisture resistance can be applied during or after the spinning operation.

Embossing and Other Techniques

Decorative papers can be produced by embossing in a variety of patterns. Embossing does not usually improve strength significantly. Embossing or "dimpling" in certain patterns, followed by lamination, can produce composites with added strength as well as bulk and thermal insulation.

Other mechanical methods include (1) shredding for bulk or padding; (2) pleating, used as a forming aid and for strength in paper cups and plates; (3) die cutting and punching; and (4) molding, which consists of compressing the wet pulp web in a mold to form a finished shape, such as an egg crate.

Applications

As an engineering material, paper has several important applications.

As filtration material, paper can be used either as a labyrinth barrier material to guide the fluid or gas to be filtered or, more commonly, as the filtering medium itself. Paper is used for filtering automotive air and oil, and air in room air conditioners, as well as for industrial plant filtration, filtering liquids in teabags, in addition to machine-cooling oil and domestic hot water filters.

Papers are used for both light- and heavy-duty gaskets, for such applications as high- and low-pressure steam and water, high- and low-temperature oil, aromatic and nonaromatic fuel systems, and sealing both rough and machined surfaces.

Electrical insulation represents one of the largest engineering uses of papers. For electrical uses, special types include coil papers or layer insulation, cable paper or turn insulation, capacitor papers, condenser papers, and high-temperature, inorganic insulating papers.

A large and growing use for paper is in structural sandwich materials, where papers are impregnated with a resin such as phenolic

P

and formed in the shape of a honeycomb. The honeycomb is used as a core between facing sheets of a variety of materials including paperboard, reinforced plastics, and aluminum.

Another large-volume application of papers is as backing material for decorative films or other surfacing materials. These provide bulk and depth to the product in simulating leather or fabrics.

Paper Plants

Cellulose for papermaking is obtained from a wide variety of plant life, made directly into *paper pulp*, or obtained from old rags that were originally made from vegetable fibers. Animal fibers incorporated into some papers are fillers for special purposes, not papermaking materials. *Rice paper* of China came from the *Tetrapanax papyriferum*, but the so-called rice paper used for cigarettes in the United States is made from flax fiber. *Cigarette paper* is also made from ramie and sunn hemp. The distinction between cigarette paper and the tissue paper used for wrapping is that it must be free of any substance that would impart a disagreeable flavor to the smoke, and it must be opaque and pure white, must burn at the same rate as tobacco, and must be tasteless.

Wood pulp is now the most important papermaking material. Spruce is the chief wood used for the sulfite process, but hemlock and balsam fir are also used. Aspen and other hardwoods are used in the soda process, and also southern pine. White fir is readily pulped by any process, but western red cedar is high in lignin content, about 30%, and reduced with difficulty by the sulfate process to a dark-colored pulp. It is pulped by the kraft process. Its fibers are fine and short, yielding a paper of high bursting strength. Normally, the *pulpwoods* of the West Coast are western hemlock, white fir, and Sitka spruce, leaving the Douglas fir to the lumber mills. Western hemlock, balsam, and spruce are the chief pulpwoods of Canada. Pines are used extensively in the United States, especially for kraft paper, paperboard, and book paper. More than 50% of all pulpwood used in United States is now from the southern states, and about 10% of this is salvage from lumber mills. But, in general, special methods are used for pulping pine since conventional sulfite liquor does not free the fibers as the phenolic compounds in the heartwood condense to form insoluble compounds.

Kraft paper is sulfate-pulped from a mixture of 50% western hemlock, 25% western red cedar, and 25% Douglas fir. The fir has a coarse fiber that gives high tear strength; cedar has a long, thin fiber that gives a smooth surface; and hemlock is abundant and used as a filler. Poplars are also used for pulpwood, and Scott Paper Co. uses fast-growing scrub alder. Newsprint made from hardwoods has a bursting strength 20% higher than that made from softwoods, and the brightness value is higher, but the pulping of hardwoods is usually a more involved chemical process.

In England, fine printing papers are made by the soda process from *esparto* grass. It gives a soft, opaque, light paper, although the cellulose content is less than 50%. Some grades of cardboard and some newsprint are made from straw. *Deluwang paper* of the East Indies is made from the scrapped and beaten bark of the *paper mulberry* tree. It is an ancient industry in Java, and the paper is used for lampshades and fancy articles. Under the name of *tapa cloth*, the sheets are dried and used as a muslinlike fabric by the Polynesians. The strips are welded together by overlapping and beating together the wet material. Bagasse is of increasing importance as a paper-making material in the sugar-growing areas of the world.

Parabolic Reflector

A reflector for ultraviolet (UV) curing of adhesives that projects parallel light beams perpendicular to the assembly, but is not focused. See also *UV electron beam-cured adhesives*.

Paraffin

A general name often applied to paraffin wax, but more correctly referring to a great group of hydrocarbons obtained from petroleum. Paraffin compounds begin with methane, CH_4 , and are sometimes called the *methane group*. The compounds in the series have the general formula $\text{C}_n\text{H}_{2n+2}$ and include gases methane and ethane; the products naphtha, benzene, gasoline, lubricating oils, and jellies; and the common paraffin. The name *paraffin* indicates little affinity for reaction with other substances. And, in practice, the name is limited to the waxes that follow petroleum jelly in the distillation of petroleum. These waxes melt at 104°F – 140°F (40°C – 60°C) and consist of the hydrocarbons between C_{22} and C_{27} ; the refined waxes may range up to 194°F (90°C). They burn readily in air. Paraffin occurs to some extent in some plant products, but its only commercial source is from natural petroleum.

Paraffin oil is drip oil from the wax presses in the process of extracting paraffin wax from the wax-bearing distillate in refining of petroleum. The oil is treated, redistilled, and separated into various grades of lubricating oils from light to heavy. They may be treated and bleached with sulfuric acid and neutralized with alkali. When decolorized with acid and sold as filtered, they are brilliant liquids, but are not suitable in places where they may be in contact with water, since the sulfo compounds present cause emulsification. *Triton oil* is 100% pure paraffin oil.

Paraffin and Whitewash Test

An early form of penetrant test in which the suspect component was immersed in paraffin, usually warm, withdrawn and wiped dry, and then painted with whitewash. Any cracks were revealed by paraffin seeping from them to stain the whitewash.

Paraffin Wax

The first distillate taken from petroleum after the cracking process is referred to as *wax bearing* and is put through a filter press and separated from the oils. The wax collected on the plates is called *slack wax*, and it contains 50% wax and 50% oil. This is chilled to free it from oil. The yellow waxes are filtered to make a white, semitranslucent, refined wax, which is odorless and tasteless. For large-scale operations, solvent methods of wax extraction are used. Paraffin waxes are soluble in ether, benzene, and essential oils.

Petrolatum is a two-phase colloidal system or gel consisting of high-molecular-weight hydrocarbon oils dispersed in microcrystalline waxes. *Wax tailing* is a name for the distillate that comes from petroleum after the wax-bearing distillate is removed. It contains no wax, but at ordinary temperatures looks like beeswax. It is very adhesive and is employed in roofings and for waterproof coatings.

Synthetic paraffin wax, called *Ruhr wax*, is made in Germany from low-grade coals and other hydrocarbon sources. They are used as additives in paper coatings and printing inks and in mixing with refined paraffin.

Ozokerite, also known as *mineral wax*, and as *earth wax*, is a natural paraffin found in Utah and in central Europe and used as a substitute or extender of beeswax and in polishes, candles, printing inks, crayons, sealing waxes, phonograph records, and insulation.

Parallel Laminate

(1) A composite laminate of woven fabric in which the plies are aligned in the same position as they were on the fabric roll. (2) A series of flat or curved cloth-resin layers stacked uniformly one on top of the other.

Paramagnetic

See *magnetic*.

Paramagnetic Material

(1) A material whose specific permeability is greater than unity and is practically independent of the magnetizing force. (2) Material with a small positive susceptibility due to the interaction and independent alignment of permanent atomic and electronic magnetic moments with the applied field. Compare with *ferromagnetic material*.

Paramagnetism

A property exhibited by substances that, when placed in a magnetic field, are magnetized parallel to the field to an extent proportional to the field (except at very low temperatures or in extremely large magnetic fields). Compare with *ferromagnetism*.

Parameter

In statistics, a constant (usually unknown) defining some property of the frequency distribution of a population, such as a population median or a population standard deviation.

Parameter (in Crystals)

See *lattice parameter*.

Parchment

Originally, goatskin or sheepskin specially tanned and prepared with a smooth, hard finish for writing purposes. It was used for legal documents, maps, and fancy books, being more durable than the old papers. The extremely thin, high-quality parchment that was used for documents and handmade books was rubbed with pumice and flattened with lead. Parchment now is usually *vegetable parchment*. It is made from a base paper of cotton rags or alpha cellulose called *water leaf* that contains no sizing or filling materials. The water leaf is treated with sulfuric acid that converts a part in the cellulose to a gelatinlike amyloid. When the acid is washed off, the amyloid film hardens on the fibers and the interstices of the paper. The strength of the paper is increased, and it will not disintegrate even when fully wet. The paper now has a wide usage in food packaging as well as for documents as a competitor of the resin-treated wet-strong papers. The wet strength and grease resistance are varied by differences in acid treatment and subsequent sizing. *Vellum* is a thick grade of writing paper made from high-grade rag pulp pebbled to imitate the original calfskin parchment called vellum.

Parent Metal

In welding, the original unjoined metal and its microstructure. See preferred term *base metal*.

Parfocal Eyepiece

Microscope eyepieces, with common focal planes, which are interchangeable without refocusing.

Parfocal Lenses

Lenses that have the same focal length so that they can be interchanged without the need to refocus the microscope or other optical equipment.

Parison

The hollow plastic tube for which a plastic component is blow molded. See also *blow molding*.

Parison Swell

In blow molding of plastics, the tendency of the *parison* to enlarge as it emerges from the die. It is expressed as the ratio of the cross-sectional area of the parison to the cross-sectional area of the die opening. See also *blow molding*.

Parkerizing

A proprietary treatment for forming corrosion-resistant phosphate conversion coating on steel.

Parkes Process

A process used to recover precious metals from lead and based on the principle that if 1% to 2% zinc is stirred into the molten lead, a compound of zinc with gold and silver separates out and can be skimmed off.

Partial Annealing

An imprecise term used to denote a treatment given cold-worked metallic material to reduce its strength to a controlled level or to affect stress relief. To be meaningful, the type of material, the degree of cold work, and the time–temperature schedule must be stated.

Partial Hydrodynamic Lubrication

See *quasihydrodynamic lubrication*.

Partial Joint Penetration

Weld joint penetration which is less than complete. Compare with *complete joint penetration*.

Partial Journal Bearing

A bearing in which the bore extends not more than half the circumference of the journal.

Partial Pressure

The pressure exerted by individual gases in a mixture.

Partially Stabilized Zirconia

Zirconia (ZrO_2) that contains a mixture of cubic and tetragonal and/or monoclinic phases produced by the addition of small amounts of magnesium oxide (MgO), calcium oxide (CaO), or yttrium oxide (Y_2O_3). These materials are used in structural applications where

P

their high strength (600–700 MPa, or 87–100 ksi) and moderate fracture toughness (11–14 MPa√m, or 10–13 ksi√in.) can be exploited. See also *zirconia*.

Particle

- (1) Any small part of matter, such as a molecule, atom, or electron.
- (2) Any small subdivision of matter, such as a metal or ceramic powder particle.

Particle Accelerator

A device that raises the velocities of charged atomic or subatomic particles to high values.

Particle Hardness

The hardness of an individual ceramic or metal powder particle as measured by a Knoop- or Vickers-type microhardness indentation test.

Particle Morphology

The form and structure of an individual metal or ceramic powder particle.

Particle Shape

The appearance of a metal particle, such as spherical, rounded, angular, acicular, dendritic, irregular, porous, fragmented, blocky, rod, flake, nodular, or plate.

Particle Size

The controlling lineal dimension of an individual particle as determined by analysis with screens or other suitable instruments. See also *sieve analysis* and *sieve classification*.

Particle Size Analysis

See preferred term *sieve analysis*.

Particle Size Classification

See preferred term *sieve classification*.

Particle Size Distribution

The percentage, by weight or by number, of each fraction into which a powder or sand sample has been classified with respect to sieve number or *particle size*. See *sieve classification*.

Particle Size Range

- (1) The limits between which variation in particle size is allowed.
- (2) Classification of spray powders defined by an upper and lower size limit; for example, –200 + 300 mesh: a quantity of powder, the largest particles of which will pass through a 200-mesh sieve and the smallest of which will not pass through a 325-mesh sieve. See also *sieve analysis* and *sieve classification*.

Particle Sizing

Segregation of granular material into specified particle size ranges.

Particle Spacing

The distance between the surfaces of two or more adjacent particles in a loose powder or a compact.

Particle-Induced x-Ray Emission

A method of trace elemental analysis in which a beam of ions (usually protons) is directed at a thin foil on which the sample to be analyzed has been deposited; the energy spectra of the resulting x-rays is measured. See also *particle accelerator* and *proton*.

Particulate Composite

Material consisting of one or more constituents suspended in a matrix of another material. These particles are either metallic or nonmetallic.

Particulates

Particulates are solids or liquids in a subdivided state. Because of this subdivision, particulates exhibit special characteristics that are negligible in the bulk material. Normally, particulates will exist only in the presence of another continuous phase, which may influence the properties of the particulates. A particulate may comprise several phases. They can be categorized into particulate systems that relate them to commonly recognized designations. Fine-particle technology deals with particulate systems in which the particulate phase is subject to change or motion. Particulate dispersions in solids have limited specialized properties and are conventionally treated in disciplines other than fine-particle technology.

The universe is made up of particles, ranging in size from the huge masses in outer space (such as galaxies, stars, and planets) to the known minute building blocks of matter (molecules, atoms, protons, neutrons, electrons, neutrinos, and so on). Fine-particle technology is concerned with those particles that are tangible to human senses, yet small compared to the human environment—particles that are larger than molecules but smaller than gravel. Fine particles are in abundance in nature (as in rain, soil, sand, minerals, dust, pollen, bacteria, and viruses) and in industry (as in paint pigments, insecticides, powdered milk, soap, powder, cosmetics, and inks). Particulates are involved in such undesirable forms as fumes, fly ash, dust, and smog and in military strategy in the form of signal flares, biological and chemical warfare, explosives, and rocket fuels.

Processing and Uses

There are many cases where a particulate is either a necessary or an inadvertent intermediary in an operation. Areas that may be involved in processing particulates may be classified as follows:

Size reduction

Mechanical (starting with bulk material)

Grinding

Atomization

Emulsification

Physicochemical (conversion to molecular dispersion)

Phase change (spray drying, condensation)

Chemical reaction

Size enlargement (agglomeration, compaction)

Pelletizing

Briquetting

Nodulizing

Sintering

Separation or classification

Ore beneficiation

Protein shift

Deposition (collection, removal)*Coating or Encapsulation**Handling*

Powders

Gas suspensions (pneumatic conveying)

Liquid suspensions (non-Newtonian fluids)

End products in which particulate properties themselves are utilized include the following:

Mass or heat-transfer agents (used in fluidized beds)*Recording (memory) agents*

Electrostatic printing powders and toners (for optical images)

Magnetic recording media (for electronic images)

Coating agents (paints)*Nucleating agents**Control agents* (for servomechanisms)

Electric fluids

Magnetic fluids

Charge carriers (used in propulsion, magnetohydrodynamics)*Chemical reagents*

Pesticides, fertilizers

Fuels (coal, oil)

Soap powders

Drugs

Explosives

*Food products***Characterization**

The processing or use of particulates will usually involve one or more of the following characteristics:

Physical

Size (and size distribution)

Shape

Density

Packing or concentration

Chemical

Composition

Surface character

Physiochemical (including adhesive, cohesive)*Mechanical or dynamic*

Inertial

Diffusional

Fluid drag

Dilute suspensions (Stokes' law, Cunningham factor, drag coefficient)

Concentrated suspensions (hindered settling, rheology, fluidization)

Optical (scattering, transmission, absorption)

Refractive index (including absorption)

Reflectivity

Electrical

Conductivity

Charge

*Magnetic**Thermal*

Insulation (conductivity, absorptivity)

Thermophoresis

Many of the characteristics of particulates are influenced to a major extent by the particle size. For this reason, particle size has been accepted as a primary basis for characterizing particulates. However, with anything but homogeneous spherical particles, the measured "particle size" is not necessarily a unique property of the particulate but may be influenced by the technique used. Consequently, it is important that the techniques used for size analysis be closely allied to the utilization phenomenon for which the analysis is desired.

Particle Size

Size is generally expressed in terms of some representative, average, or effective dimension of the particle. The most widely used unit of the particle size is the micrometer (μm), equal to 0.001 mm. Another common method is to designate the screen mesh that has an aperture corresponding to the particle size. The screen mesh normally refers to the number of screen openings per unit length or area; several screen standards are in general use; the two most common in the United States are the U.S. standard and the Tyler standard screen scales.

Particulate systems are often complex. Primary particulates may exist as loosely adhering (as by van der Waals forces) particles called flocs or as strongly adhering (as by chemical bonds) particulates called agglomerates. Primary particles are those whose size can only be reduced by the forceful shearing of crystalline or molecular bonds. Some particulates can be dispersed and can be reversed with application of light shearing forces.

Parting

(1) In the recovery of precious metals, the separation of silver from gold. (2) The zone of separation between *cope* and *drag* portions of the mold or flask in sand casting. (3) A composition sometimes used in sand molding to facilitate the removal of the pattern. (4) Cutting simultaneously along two parallel lines or along two lines that balance each other in side thrust. (5) A shearing operation used to produce two or more parts from a stamping.

Parting Agent

See *mold release agent*.

Parting Compound

A material dusted or sprayed on foundry (casting) patterns to prevent adherence of sand and to promote easy separation of *cope* and *drag* parting surfaces when the cope is lifted from the drag.

Parting Line

(1) The intersection of the parting plane of a casting or plastic mold or the parting plane between forging dies with the mold or die cavity.

P

(2) A raised line or projection on the surface of a casting, plastic part, or forging that corresponds to the said intersection.

Parting Sand

In foundry practice, a fine sand for dusting on sand mold surfaces that are to be separated.

Partition Coefficient

See *partition law*.

Partition Law

This states that “the concentrations of any individual molecular species into immiscible phases maintain a constant ratio to each other at constant temperature.” It is of course implicit that the two phases are sufficiently mixed or otherwise in contact for a time sufficient for equilibrium to be reached. The ratio of the two concentrations is the partition coefficient or distribution ratio.

Parts Former

A type of upsetter designed to work on short billets instead of bars and tubes, usually for cold forging.

Parts Per Billion

A measure of proportion by weight, equivalent to one unit weight of a material per billion (10^9) unit weights of compound.

Parts Per Million

A measure of proportion by weight, equivalent to one unit weight of a material per million (10^6) unit weights of compound.

PAS

See *polyaryl sulfone*.

Pascal

The SI unit of pressure, stress. $1 \text{ Pa} = 1 \text{ N/m}^2$. 1 N (Newton, the unit of force) = 0.224809 lbf.

Pass

(1) One movement of the material through a pair of rolls or alternatively through the series of pairs of rolls comprising a rolling mill. (2) One line of one layer of weld deposit. Some processes such as the metal inert gas process can deposit a complete pass without interruption, but in the manual metallic arc process, a number of electrodes may be required to make one pass. (3) The open space between two grooved rolls through which metal is processed. See also *weld pass*.

Pass Sequence

See *deposition sequence*.

Passivation

(1) A reduction of the anodic reaction rate of an electrode involved in corrosion. (2) The process in metal corrosion by which metals become *passive*. (3) The changing of a chemically active surface of a metal to a much less reactive state. Contrast with *activation*. (4) The formation of an insulating layer directly over the semiconductor surface to protect the surface from contaminants, moisture, and so forth.

Passivator

A type of corrosion *inhibitor* that appreciably changes the potential of a metal to a more noble (positive) value.

Passive

(1) A metal corroding under the control of a surface reaction product. (2) The state of the metal surface characterized by low corrosion rates in a potential region that is strongly oxidizing for the metal. (3) Generally, a metal not reacting significantly with the environment, particularly in electrochemistry. More specifically, a metal that can be reactive with the environment but that has developed some surface characteristic such as a protective oxide film that prevents further attack.

Passive–Active Cell

A corrosion cell in which the *anode* is a metal in the *active* state and the *cathode* is the same metal in the *passive* state.

Passivity

A condition in which a piece of metal, because of an impervious covering of oxide or other compound, has a *potential* much more positive than that of the metal in the active state.

Paste

An adhesive compound having a characteristic plastic-type consistency, that is, a high order of yield value, such as that prepared by heating a mixture of starch and water and subsequently cooling the hydrolyzed product. See also *adhesive*, *glue*, *mucilage*, and *sizing*.

Paste Brazing Filler Metal

A mixture of finely divided brazing filler metal with an organic or inorganic flux or neutral vehicle or carrier. Brazing paste mixtures are usually prepared for *furnace brazing* in a *protective atmosphere*.

Paste Extrude

An extrusion method for plastics in which the executable material, a fine powder form mixed with a lubricant, is forced through a die of given size, without heat, as opposed to melt extrude. See also *extruder* (plastics).

Paste Soldering Filler Metal

A mixture of finely divided metallic solder with an organic or inorganic flux or neutral vehicle or carrier.

Pasteboard

A class of thick paper used chiefly for making boxes and cartons and for spacing and lining. It may be made by pasting together several single sheets, but more usually by macerating old paper and rolling into heavy sheets. It may also be made of straw, certain grasses, and other low-cellulose paper materials, and it is then known as *strawboard*. Colloquially, the term *pasteboard* applies to any paper stock board used for making boxes, including the hard and stiff boards made entirely from pulp, but the term *pasteboard* is not liked in the paper industry. The bulk of packaging boards are now pulp boards treated with resin and are called *carton boards*. *Cardboard* is usually a good-quality chemical pulp or rag pasteboard used for cards, signs, or printed material or for the best-quality boxes. Ivory board, for art printing and menu cards, is a highly finished cardboard clay coated on both sides. *Jute board*, used for folding boxes, is a regular product of the paper mills and is a strong, solid board made of kraft pulp. *Chipboard* is a cheap board made from mixed scrap paper, used for boxes and book covers. When made with a percentage of mechanical wood pulp, it is called *pulpboard*. A heavy, rope-pulp paper or board, usually reddish and used for large expansion filing envelopes, is called *paperoid*.

Pastes

Conductor, resistor, dielectric, seal glass, polymer, and soldering compositions are available in paste or ink form. They are used to produce hybrid circuits, networks, and ceramic capacitors. The materials are often called thick-film compositions.

Types

Conductor pastes consist of metallic elements and binders suspended in an organic vehicle. Primarily, precious metals such as gold, platinum, palladium, silver, copper, and nickel are used singularly or in combination as the conductive element. The adhesion mechanism to the substrate is provided by either a frit bond, reactive bond, or mixed bond.

Important properties of conductor pastes include wire bondability, conductivity, solderability, solder leach resistance, and line definition.

Thick-film resistor plates are composed of a combination of class frit, metal, and oxides. These pastes are used in microcircuits, voltage dividers, resistor networks, chip resistors, and potentiometers.

Dielectric compounds are used as insulators for the fabrication of multilayer circuits and crossovers or as protective coverings.

Solder pastes are one of the more common component attach products. They consist of finely divided solder powders of all common alloys of tin, lead, silver, gold, etc., suspended in a vehicle-flux system. The fluxes may be nonactivated or completely activated. The most popular is RMA (rosin, mildly activated).

Patent Leveling

Same as *stretcher leveling*.

Patenting

An isothermal heat treatment process applied to medium- and high-carbon steel wire prior to its final drawing operation. The steel is heated to the austenitic region, typically 950°C, and then cooled to about 480°C–550°C in a salt or lead bath to produce structure of upper bainite, that is, ferrite with a fine distribution of carbide; see *steel*. This has a very high ductility and can be cold drawn with total reductions in diameter of 90%, nearly double that possible with annealed wire. This produces a wire with very high tensile strength, in excess of 1600 MPa, 230,000 psi, with adequate ductility.

Patina

(1) Generally, surface discoloration or a coating arising from atmospheric deposition or corrosion. The term usually implies that the effect is more decorative than deleterious; in some cases, it may even be induced by chemical treatment. More specifically, the term refers to the green corrosion product formed on copper- and sulfur-rich atmospheres. (2) Also used to describe the appearance of a weathered surface of any metal.

Pattern

(1) A form of wood, metal, or other material around which molding material is placed to make a mold for casting metals. (2) A form of wax- or plastic-base material around which refractory material is placed to make a mold for casting metals. (3) A full-scale reproduction of a part used as a guide in cutting.

Pattern Draft

In foundry practice, the paper allowed on the vertical faces of a pattern to permit easy withdrawal of the pattern from the mold or die.

Pattern Layout

A full-size drawing of a foundry (casting) pattern showing its arrangement and structural features.

Pattern Metals

Various low melting temperature alloys used for patterns. They are cast in a master mold or die, and, after the working mold has been formed around them, they are melted and poured out for reuse.

Patternmaker's Allowance

See *shrinkage allowance*.

Patternmaker's Rule (r)

A rule (r) with calibrations oversize by the shrinkage allowance appropriate to the intended cast metal.

Patternmaker's Shrinkage

Contraction allowance made on patterns to compensate for the decrease in dimensions as the solidified casting cools in the mold from the freezing temperature of the metal to room temperature.

P

The pattern is made larger by the amount of contraction that is characteristic of a particular metal to be used. See *shrinkage*.

Pattinson Process

A process for separating silver from lead, in which the molten lead is slowly cooled so that crystals poorer in silver solidify out and are removed, leaving the melt richer in silver.

Pauli Exclusion Principle

An electron state can contain no more than two electrons and they will have opposite spins.

PBI

See *polybenzimidazole*.

PBT

See *polybutylene terephthalate*.

PC

See *polycarbonates*.

Peak Overlap

In materials characterization techniques such as electron probe x-ray microanalysis or Auger electron spectroscopy, the formation of a single peak when two closely spaced x-ray peaks cannot be resolved; the energy (or wavelength) of the peak is some average of the characteristic energies (or wavelengths) of the original two peaks. See also *full width at half maximum*.

Pearlite

A metastable lamellar aggregate of *ferrite* and *cementite* resulting from the transformation of *austenite* at temperatures above the *bainite* range. The iron/iron carbide eutectoid. See *steel*.

Pearlitic Iron/Steel

See *cast iron and steel*.

Pearlitic Malleable

See *malleable cast iron*.

Pearlitic Structure

A microstructure resembling that of the pearlite constituent in steel. Therefore, it is a lamellar structure of varying degrees of coarseness.

Pebble Surface/Pebbling

A rounded surface texture similar to, but usually coarser than, orange peel effect.

Pebbles

See *orange peel (metals)*.

Pedestal Bearing

A bearing that is supported on a column or pedestal rather than on the main body of the machine.

PEEK

See *polyether ether ketone*.

Peel Ply

In composites fabrication, a layer of open-weave material, usually fiberglass or heat set nylon, applied directly to the surface of a prepreg lay-up. The peel ply is removed from the cured laminate immediately before bonding operations, leaving a clean, resin-rich surface that needs no further preparation for bonding, other than the application of a primer if one is required. See also *lay-up* and *prepreg*.

Peel Strength (Adhesives)

The average load per unit width of bond line required to separate progressively one member from the other over the adhered surfaces at a separation angle of approximately 180° in a separation rate of 152 mm (6 in.) per minute. It is expressed in force per unit width of specimen (N/mm, or lbf/in.).

Peel Test (Adhesives)

See *peel strength (adhesives)*.

Peel Test (Weldments)

(1) A destructive method of inspection that mechanically separates a lap joint by peeling. (2) A test of spot, seam, and projection welds in which the two joined components are pried or peeled apart in such a manner that the parting load is carried by individual spot welds or at one point on the seam. Also termed a *slug test*.

Peeling

The detaching of one layer of a coating from another, or from the base metal, because of poor adherence.

Peen Plating

See *tumbling*.

Peening

Repeated local impacting to produce plastic deformation of the surface layers. It may be performed by handheld, round-end hammer, for example, on weld deposits and the adjacent areas. Alternatively, the component, or specific areas, may be bombarded with peening shot in automatic machines, termed *shot peening*. Performed correctly, peening induces beneficial compressive residual stresses in the surface although there are balancing tensile stresses below. Significant deformation, deliberate or otherwise, can occur in thin

components. Peening aims to deform the surface to a carefully judged extent but without scratches or notches. Consequently, the shot is spherical and of controlled size, and broken particles are removed to avoid surface damage. In contrast, shot blasting is a relatively crude process intended to remove surface scale or to roughen the surface and accordingly may use broken, irregular shot or even angular, sharp edged grit.

Peening Wear

Removal of material from a solid surface caused by repeated impacts on very small areas.

PEI

See *polyetherimide*.

Peierls/(Nabarro) Force

The force necessary to move a dislocation from one equilibrium position to another.

Pellet

In powder metallurgy, a small rounded or spherical solid body that is similar to a shotted particle. See also *shotting*.

Pellini Drop Test

A comparative test of the brittle fracture resistance of plate or strip. The test piece comprises a full thickness strip having, on one face, a brittle weld deposit notched to a depth corresponding with the original plate face. It is supported, notched down, at its two ends and impacted on its centerline by a falling weight. A key feature is that the height of the supports is selected so O'Reilly deflection of the plate of 5° at the stage where the specimen face contacts the rig base. The weld is judged to initiate a crack at 3° deflection, and hence, the test determines whether the plate can deflect a further 2° without fracturing at the test temperature.

Pellini Explosive Test

Similar in concept to the *Pellini drop test* except that the load is applied by the shock wave from an explosion and the explosive charge is shaped and positioned to apply load over a large area of the specimen rather than just the centerline.

Peltier Effect

The release or absorption of heat as an electric current crosses the junction from one conductor to a dissimilar one. See *thermoelectric effect*.

Penetrameter

A device for assessing sensitivity in radiography. It comprises a stepped plate or a stepped series of holes in a plate, and it is placed on the component under test during irradiation. The extent to which the steps can be resolved indicating the size of defect that can be detected.

Penetrant

A liquid with low surface tension used in *liquid penetrant inspection* to flow into surface openings of parts being inspected. See *dye penetrant*.

Penetrant Inspection

See preferred term *liquid penetrant inspection*.

Penetration (Adhesives)

The entering of an adhesive into an adherend. This property of a system is measured by the depth of penetration of the adhesive into the adherend.

Penetration (Metals)

(1) In founding, an *imperfection* on a casting surface caused by metal running into voids between sand grains, usually referred to as *metal penetration*. (2) In welding, the distance from the original surface of the base metal to that point at which fusion ceased. (3) In spot, seam welds, etc., the depth of the nugget measured from the interface. See also *joint penetration* and *root penetration*.

Penetration (of a Grease)

The depth in 1/10 mm that a standard cone penetrates the sample in a standard cup under prescribed conditions of weight, time (5 s), and temperature (25°C or 77°F). The result depends on whether or not the grease has been subjected to shear. In unworked penetration, the grease is transferred with as little deformation as possible or is tested in its container. In worked penetration, the grease is subjected to 60 double strokes in a standard device. In prolonged worked penetration, the grease is worked for a specified period before the 60 strokes. The results may be quoted as penetration number or penetration value.

Penetration Bead/Run/Pass (of Weld)

The first run of a multiple run weld deposited from one side that penetrates and fully fuses the root.

Penetration Hardness

Same as *indentation hardness*.

Penetration Hardness Number

Any numerical value expressing the resistance of a body to the penetration of a second, usually harder, body.

Penetrometer

In grease technology, an instrument for measuring the consistency of a grease by allowing a cone to penetrate into the grease under control conditions. See also *penetration (of a grease)*.

Percent Conductivity

The conductivity of a material expressed as a percentage of that of copper. See also *IACS*.

P

Percent Error

In the case of a mechanical testing machine, the ratio, expressed as a percentage, of the error to the correct value of the applied load.

Percent Ferrite

See preferred term *ferrite number*.

Percent Theoretical Density

See *density ratio*.

Percentage

The proportion relative to one hundred.

Percentile

The boundary line cutting off the indicated percentage. For example, a large number of creep rupture tests performed under identical conditions will fail after a wide scatter of lives. The 5 percentile line is the line drawn to exclude the 5% that failed in the shortest time.

Percussion Cone

Damage produced by contact stresses generated by mechanical contact of a hard, blunt object with a glass surface. Typically, it has the appearance of a semicircular or circular crack on the damaged surface, propagating into the glass, flaring out with increasing depth into a cone-shaped crack. Also called impact bruise, butterfly bruise, bump check, and Hertzian cone crack.

Percussion Welding

A resistance welding process that produces coalescence of abutting surfaces using heat from an arc produced by a rapid discharge of electrical energy. Pressure is applied percussively during or immediately following the electrical discharge.

Perforating

The punching of many holes, usually identical and arranged in a regular pattern, in a sheet, workpiece blank, or previously formed part. The holes are usually round, but may be any shape. The operation is also called multiple punching. See also *piercing*.

Perfume Oils

Volatile oils obtained by distillation or by solvent extraction from the leaves, flowers, gums, or woods of plant life, although a few are of animal origin. Perfumes have been used since the earliest times, not only for aesthetic value but also for antiseptic value and for religious purposes. Simple perfumes usually take their names from the name of the plant, but the most esteemed perfumes are blends, and the blending is considered a high art. It is done by tones imparted by many ingredients. Some oils with repugnant odors have an attractive fragrance in extreme dilution and a persistence that is valued in blends and for stabilization. Some oils with heavy odors, such as *coumarin*, are used in dilution to give body. Since many of the odors come directly from esters, aldehydes, and ketones, they can be made synthetically from coal-tar hydrocarbons and alcohols. Synthetics are now most used in perfumes, although some natural

odors have not yet been duplicated synthetically, and about 30,000 aromatics have been developed. A perfume may contain 50 components, sometimes as high as 300, and the average perfume manufacturer employs about 3000 components. Some of the chemicals are not odors, but give lasting qualities or enhance odor. Some are used as fixatives or blending agents. *Hydroquinone dimethyl ether* has an odor of sweet clover but is used as a fixative in other perfumes.

In general, the aldehyde odors are fugitive, and some become acid in the presence of light or oxygen. Ketones are more stable. Esters are usually stable, but some are saponified in hot solution and cannot be used for soaps. Some esters, made from complex high alcohols, are used to give a fresh top note to floral perfumes. *Linalyl acetate*, produced from citral, is an example. Acid perfumes neutralize free alkali and cannot be used in soaps. Phenol odors alter the color of soaps, and the odor may also become disagreeable.

Some odors are never extracted from the flowers, but are compounded. *Crab apple*, for example, which is a peculiarly sweet odor, is compounded of 16 oils, including bois de rose, ylang-ylang, nutmeg oil, jasmine, musk, heliotropin, and coumarin. *Wisteria* is the honey-like odor of the mauve and white flowers of the climbing plant *Wisteria sinensis*. The oil is never extracted but is compounded from geranium, Peru balsam, benzoin, bois de rose, and synthetics. Some oils, such as *lavender*, have no value when used alone but require skillful blending to develop the pleasant odor. Apple and peach odors are *allyl cinnamate*. Synthetic *rose* is the ester of phenyl ethyl alcohol made from benzene and ethylene oxide. Although the natural rose odor is readily extracted, it is more expensive.

Fixatives are used for the finer perfumes. They are essential oils that are less volatile and thus delay evaporation. The animal oils, such as musk and civet, are of this class, and also the balsam oils. Musk is from the male musk deer of Tibet. It is one of the most expensive materials. Synthetic musk is as powerful as the natural. The synthetic musk of DuPont is called *astrotone*.

Versilide is a cyclic ketone synthetic musk that is very stable in soaps and cosmetics and does not discolor.

Attar of rose is one of the most ancient and popular perfume oils. The name is derived from the Persian *attar* and is sometimes incorrectly given as *ottar* but with the same French pronunciation. The finest attar of rose is from Bulgaria, where it is distilled from the flowers of the *damask rose*. The fresh oil is colorless but turns yellowish green. In France, the oil is obtained from the *Rosa centifolia*. *Rosewater* is the scented water left after distillation or is made by dissolving attar in water.

As with jewelry, the manufacture of perfumes is normally classified as a luxury industry. But the vital test of essentiality comes in wartime, and these anesthetic materials are always considered essential to the public morale, and hence basic. Even under desperate wartime conditions, France never stopped the manufacture of perfumes, and during the life struggle of England in World War II, the restrictive regulations placed upon perfume manufacture had to be abandoned quickly because of public pressure. Wartime restrictions placed on the imports of perfume oils into the United States during World War II were immediately abandoned.

Period/Periodicity (of Elements)

See *atomic structure* and *periodic table*.

Periodic Reverse

Pertains to periodic changes in the direction of flow of the current in electrolysis. It applies to the process and also the machine that controls the time for both directions.

Periodic Table

A table of the elements presented in periods, that is, with elements having similar chemical characteristics arranged in vertical rows. See *atomic structure*.

Peripheral Clearance Angle

See *clearance angle*.

Peripheral Milling

Milling a surface parallel to the axis of the cutter. See also *milling* and *milling cutter*.

Peripheral Speed

See preferred term *cutting speed*.

Peritectic

An isothermal reversible reaction in metals in which a liquid phase reacts with a solid phase to produce a single (and different) solid phase on cooling.

Peritectic Equilibrium

A reversible univariant transformation in which a solid phase stable only at lower temperature decomposes into a liquid and a solid phase that are conjugate at higher temperature.

Peritectoid

An isothermal reversible reaction in which a solid phase reacts with a second solid phase to produce a single (and different) solid phase on cooling.

Peritectoid Equilibrium

A reversible univariant transformation in which a solid phase stable only at low temperature decomposes with rising temperature into two or more conjugate solid phases.

Permanence

(1) The property of a plastic that describes its resistance to appreciable change in characteristics with time and environment. (2) The resistance of an adhesive bond to deteriorating influences.

Permanent Load

The loading due to self weight and other nonvarying sources as opposed to additional loads due to varying applied loads.

Permanent Magnet Materials

Permanent magnet is the term used to describe solid materials capable of being magnetized permanently because of their ability to retain induced magnetization and magnetic poles after removal of externally applied fields. Such materials, which are characterized by their high magnetic induction, high resistance to demagnetization,

and maximum energy content, include a variety of alloys, intermetallics, and ceramics. Commonly included are certain steels, alnico (a cast or sintered iron-base alloy containing 7%–10% Al, 15%–19% Ni, 13%–35% Co, 3%–4% Cu, with an optional 1%–5% Ti); Cunife (60Cu–20Ni–20Fe); Fe–Co alloys containing vanadium or chromium, platinum–cobalt, and hard ferrites ($\text{SrO-Fe}_2\text{O}_3$ or $\text{BaO-6 and Fe}_2\text{O}_3$); cobalt–rare earth alloys (SmCo_5 or $\text{Sm}_2\text{Co}_{17}$); and Nd–Fe–B alloys made by powder-metallurgy processing. Each type of magnet material possesses unique magnetic and mechanical properties, corrosion resistance, temperature sensitivity, fabrication limitations, and cost. These factors provide designers with a wide range of options in designing magnetic parts.

Permanent magnet materials are based on the cooperation of atomic and molecular moments within a magnet body to produce a high magnetic induction. This induced magnetization is retained because of a strong resistance to demagnetization. These materials are classified as ferromagnetic or ferrimagnetic and do not include diamagnetic or paramagnetic materials. The natural ferromagnetic elements are iron, nickel, and cobalt. Other elements, such as manganese or chromium, can be made ferromagnetic by alloying to induce proper atomic spacing. Ferromagnetic metals are combined with other metals or with oxides to form ferrimagnetic substances; ceramic magnets are of this type.

Uses

Permanent magnet materials are marketed under a variety of trade names and designations throughout the world. Over the years, the number and range of applications utilizing permanent magnets has increased dramatically. Some of the more predominant applications include aircraft magnetos, alternators, magnetos for lawnmowers, garden tractors, and outboard motors, small and large direct current (dc) motors (including automotive motors), acoustic transducers, magnetic couplings, magnetic resonance imaging, magnetic focusing systems, ammeters and voltmeters, and watt-hour meters.

Permanent Mold

A metal, graphite, or ceramic mold (other than an ingot mold) of two or more parts that is used repeatedly for the production of many *castings* of the same form. Liquid metal is usually poured in by gravity.

Permanent Mold Castings

Permanent mold casting is performed in a mold, generally made of metal, which is not destroyed by removing the casting. Several types of casting can be included in the description of pressure die casting, centrifugal casting, and gravity die casting.

Advantages and Disadvantages

Gravity die castings are dense and fine grained and can be made with better surfaces and closer tolerances than sand castings. Tolerances are wider than for pressure die castings and plaster mold castings, but narrower than for sand castings. Production rates are lower than those obtainable by die casting.

The process stands somewhere between sand and die casting with respect to possible complexity, dimensional accuracy, mold or die casts, etc. For many parts, it provides an attractive compromise when the ultimate—whether in complexity of one-piece construction, narrow tolerances, or ultrahigh production rates—need not be met.

P

Casting Alloys

Lead-, zinc-, aluminum-, magnesium-, and copper-base alloys, as well as gray cast iron, can be cast by permanent molding. Less than 1% of total gray iron production is permanent mold cast, 5%–7% of copper and magnesium alloy, and up to 40% of total aluminum casting production. Here's a breakdown of problems to expect:

Gray iron: Mechanical properties depend on thickness.

Aluminum: Gates must be made larger to take the low specific gravity of aluminum into account.

Magnesium: Extreme caution is needed when removing metal from the furnace. Ladles must be kept at red heat to exclude moisture and prevent an explosion.

Copper: Aluminum bronze is the most popular permanent-mold-cast copper-base alloy. Turbulence must be prevented in the die cavity to reduce oxidation of the molten metal during solidification.

Permanent Set

The deformation remaining after a specimen has been stressed a prescribed amount in tension, compression, or shear for a specified time period and released for a specified time period. For the test, the residual unrecoverable deformation after the load causing the creep has been removed for a substantial and specified period of time. Also, the increase in length, expressed as a percentage of the original length, by which an elastic material fails to return to its original length after being stressed for a standard period of time.

Permeability

(1) The passage or diffusion (or rate of passage) of a gas, vapor, liquid, or solid through a material (often porous) without physically or chemically affecting it; the measure of fluid flow (gas or liquid) through a material. (2) A general term used to express various relationships between magnetic induction and magnetizing force. These relationships are either "absolute permeability," which is a change in magnetic induction divided by the corresponding change in magnetizing force, or "specific (relative) permeability," the ratio of the absolute permeability to the permeability of free space. (3) In metal casting, the characteristic of molding materials that permit gas is to pass through them. "Permeability number" is determined by a standard test.

Permeability Alloys

This is a general name for a group of nickel-iron alloys with special magnetic properties. These soft magnetic materials possess a magnetic susceptibility much greater than iron. An early alloy was composed of 78.5% nickel and 21.5% iron. It also contained about 0.37% cobalt, 0.1% copper, 0.04% carbon, 0.03% silicon, and 0.22% manganese. It is produced sometimes with chromium or molybdenum, under the name of permalloy, and is used in magnetic cores for apparatus that operates on feeble electric currents and in the loading of submarine cables. It has very little magnetic hysteresis.

Types and Uses

Supermalloy for transformers contains 79% nickel, 15% iron, 5% molybdenum, and 0.5% manganese, with total carbon, silicon, and sulfur kept below 0.5%. It is melted in vacuum and poured in an

inert atmosphere. It can be rolled as thin as 0.00064 cm. The alloy has an initial permeability 500 times that of iron.

Supremendur contains 49% iron, 49% cobalt, and 2% vanadium. It is highly malleable and has very high permeability with low hysteresis loss and high flux density. Duraperm is a high flux magnetic alloy containing 84.5% iron, 9.5% silicon, and 6% aluminum. Perminvar is an alloy containing 45% nickel and 25% cobalt, intended to give a constant magnetic permeability for variable magnetic fields. A-metal is a nickel-iron alloy containing 44% nickel and a small amount of copper. It is used in transformers and loudspeakers to give nondistortion characteristics when magnetized.

Alfenol contains no nickel, but has 16% aluminum and 84% iron. It is brittle and cannot be rolled cold, but can be rolled into thin sheets at a temperature of 575°C. It is lighter than other permeability alloys and has superior characteristics for transformer cores and tape-recorder heads. A modification of this alloy, called thermenol, contains 3.3% molybdenum without change in the single-phase solid solution of the binary alloy. The permeability and coercive force are varied by heat treatment. At 18% aluminum, the alloy is practically paramagnetic. The annealed alloy with 17.2% aluminum has constant permeability.

Aluminum-iron alloys with 13%–17% aluminum are produced in sheet form for transformers and relays. They have magnetic properties equal to the 50–50 nickel-iron alloys and to the silicon-iron alloys, and they maintain their magnetic characteristics under changes in ambient temperature.

Iron-nickel permeability alloys are used as loading in cable by wrapping layers around the full length of the cable. When nickel-copper alloys are used, they are employed as a core for the cable. Magnetostrictive alloys are iron-nickel alloys that will resonate when the frequency of the applied current corresponds to the natural frequency of the alloy. They are used in radios to control the frequency of the oscillating circuit. Magnetostriction is the stress that occurs in a magnetic material when the induction changes. In transducers, it transforms electromagnetic energy into mechanical energy. Temperature-compensator alloys are iron-nickel alloys with about 30% nickel. They are fully magnetic at –29°C but lose their magnetic permeability in proportion to rise in temperature, until, at about 54°C, they are nonmagnetic. Upon cooling, they regain permeability at the same rate. They are used in shunts in electrical instruments to compensate for errors due to temperature changes in the magnets.

Permissible Variation

In mechanical testing machines, the maximum allowable error in the value of the quantity indicated. It is convenient to express permissible variation in terms of the *percent error*. See also *tolerance*.

Permittivity

The ratio of the capacity of a condenser with and without the dielectric material in position between the plates. Also termed the *relative dielectric constant*.

Perovskites

A naturally occurring mineral with a structure type that includes no less than 150 compounds; the crystal structure is ideally cubic. Perovskites are noted for their ferroelectricity, piezoelectricity, pyroelectricity, electrostriction, high permittivity, and optical and electro-optic properties. The hardness of perovskites is approximately 5.5 on the Mohs scale.

Peroxo Compounds

Polymeric compounds containing O–O linkage.

Perpendicular Section

A section cut perpendicular to a surface of interest in a medley graphic specimen. Compare with *taper section*.

PESV

See *polyethersulfone*.

PET

See *polyethylene terephthalate*.

Petroff Equation

An equation describing the viscous power loss in a concentric bearing full of lubricant. The resisting torque on the shaft (T_0 = shear stress $\times$ shaft radius $\times$ bearing area) is given by

$$T_0 = \frac{\pi \eta N L D^2}{2c}$$

where

- π is equal to 3.1416
- η is the dynamic viscosity
- N is the shaft speed
- L is the bearing length
- D is the shaft diameter
- $2c$ is the diametrical clearance

Petrography

The study of nonmetallic matter under suitable microscopes to determine structural relationships and to identify the phases or minerals present. With transparent materials, the determination of the optical properties, such as the indices of refraction and the behavior in transmitted polarized light, is a means of identification. With opaque materials, the color, hardness, reflectivity, shape, and etching behavior in polished sections are means of identification.

Petrolatum

A jellylike substance obtained in the fractional distillation of petroleum. Its composition is between $C_{17}H_{36}$ and $C_{21}H_{44}$, and it distills off above 577°F (303°C). It is also called petroleum jelly. It is used for lubricating purposes and for compounding with rubber and resins. When highly refined for the pharmacy trade, it is used as an ointment. The specific gravity is from 0.820 to 0.865. It is insoluble in water but readily soluble in benzene and turpentine. For lubricating purposes, it should be refined by filtration only and not with acids, and it should not be adulterated with paraffin. *Sherolatam* and *Vaseline* are brands of petroleum jelly, but petroleum jellies for pharmaceutical uses may be compounded with other materials.

Petroleum

A heavy, liquid, flammable oil stored under the surface of the earth and originally formed as the by-product of the action of bacteria on marine

plants and animals. It consists chiefly of carbon and hydrogen in the form of hydrocarbons, including most of the liquids of the *paraffin series*, C_5H_{12} to $C_{16}H_{34}$, together with some of the gases, CH_4 to C_4H_{10} , and most of the solids of the series from $C_{17}H_{36}$ to $C_{27}H_{56}$. It also contains hydrocarbons of other series. While petroleum is used primarily for the production of fuels and lubricating oils, it is one of the most valuable raw materials for a very wide range of chemicals. The name *petrochemicals* is used in a general sense to mean chemicals derived from petroleum, but it does not mean any particular class of chemicals. Sulfur and helium are by-products from petroleum working.

Petroleums from different localities differ in composition, but tests of oils from all parts of the world give the limits as 83%–87% carbon and 11%–14% hydrogen, with sulfur, nitrogen, and oxygen in amounts from traces to 3%. Liquefied petroleum gases, including *propane*, *butane*, *pentane*, or mixtures, are marketed under pressure in steel cylinders as bottled gas. Propane is used in cook stoves. Butane is used to enrich illuminating and heating gas. *Liquid gas* is also used for internal combustion engines, as a solvent and for making many chemicals.

Certain highly refined oils used in medicine as laxatives and used in other specified applications are referred to as *mineral oils*. *White mineral oil* is petroleum highly refined to color. Russian and Rumanian oils with high naphthene content were particularly suitable for this refining, and the oil was called *Russian oil*. It is used as a laxative, as a carrier of many drugs, in textile spinning, as a plasticizer for synthetic resins, and for sodium dispersions where the alkali metal would normally react with any impurities.

Petroleum Oil

See *mineral oil*.

Pewter

Pewter is a very old name for tin–lead alloys used for dishes and ornamental articles; the term now refers to the use rather than to the composition of the alloy. Tin was the original base metal of the alloy, the ancient Roman pewter having about 70% tin and 30% lead, although iron and other elements were present as impurities. Pewter, or latten ware, of the sixteenth century contained as much as 90% tin, and a strong and hard English pewter contain 91% tin and 9% antimony. This alloy is easily cold-rolled and spun and can be hardened by long annealing at 225°C and quenching in cold water and tempering at 110°C. Pewter is now likely to contain lead and antimony, and very much less tin; when the proportion of tin is less than about 65%, the alloys are unsuited for vessels to contain food products, because of the separation of the poisonous lead.

Early pewter, with high lead content, darkened with age. With less than 35% lead, pewter was used for decanters, mugs, tankards, bowls, dishes, candlesticks, and canisters. The lead remained in solid solution with the tin so that the alloy was resistant to the weak acids in foods.

The addition of copper increases ductility; additions of antimony increase hardness. Pewter high (e.g., in the 91% tin and 9% antimony or antimony and copper) has been used for ceremonial objects, such as religious communion plates and chalices, and for cruets, civic symbolic cups, and flagons.

Pewter is a tin-base *white metal* containing antimony and copper. Originally, pewter was defined as an alloy of tin and lead, but to avoid toxicity and dullness of finish, lead is excluded from modern pewter. These modern compositions contain 1%–8% antimony and 0.25%–3% copper. Typical pewter products include coffee and tea services, trays, steins, candy dishes, jewelry, plates, vases, comports, and cordial cups.

P

pH

(1) The negative logarithm of the hydrogen-ion activity; it denotes the degree of acidity or basicity of a solution. At 25°C (77°F), 7.0 is the neutral value. Decreasing values below 7.0 indicate increasing acidity; increasing values above 7.0 indicate increasing basicity. The pH values range from 0 to 14. (2) The “p” derives from the German “potenz” for power and the H, obviously, from hydrogen.

Phase

A portion of a system that is chemically homogenous and physically distinct. For example, steam (liquid), water, and ice are phases of water. If a small amount of salt is dissolved in liquid water, a single phase solution will exist. However, at a certain level, the solution will be saturated and no further salt can normally be dissolved. Addition of further salt will result in two phases, the saturated solution and salt particles. In abnormal circumstances, it is possible for the amount of salt that is dissolved to exceed the saturation limit. Such solutions are termed supersaturated. Similar effects occur in solid metals where a quantity of one metal can dissolve in another to form a solid solution that is a single phase of completely uniform composition and that appears featureless under the microscope, apart from grain boundaries. The simplest case is where the two metals are completely soluble in each other at all compositions, an example being the copper–nickel system, mentioned again in later text. Most systems are, however, less simple, and, as the composition is changed, a series of different phases will be formed. In certain cases, two or more elements will combine with each other in specific ratios, for example, one atom of copper with two atoms of aluminum forms CuAl_2 . These are termed intermetallic compounds rather than solid solutions but are still phases. With many solid solutions, the solubility of the secondary component decreases as the temperature falls. If such an alloy containing the maximum amount of the second element is allowed to cool slowly, the second element will come out of solution by a precipitation process. The resultant particles or precipitates form a second phase although if cooling is rapid, precipitation may be impeded resulting in a supersaturated solid solution. A phase diagram or equilibrium diagram is a graphical presentation of the phases that are stable, under equilibrium conditions, for a range of temperatures and compositions of an alloy. The simplest phase diagram is the binary in which composition ranging from 100% of one element to 100% of the second element is plotted against temperature. The copper–nickel is an example of this simple phase diagram. More complex systems are considered in ternary diagrams (three elements), quaternary diagrams (four elements), and so on. Other forms of phase diagrams depict the phases arising under nonequilibrium conditions. See *isothermal transformation diagram*.

Phase Change

The transition from one physical state to another, such as gas to liquid, liquid to solid, gas to solid, or vice versa.

Phase Contrast (Electronic Microscopy)

(1) Contrast in high-resolution transmission electron microscope images arising from interference effects between the transmitted beam and one or more different active beams. (2) A technique of microscopical examination that utilizes the small differences in phase between light reflected from irregular surfaces to provide an image of surface features.

Phase Contrast Illumination (Optical Microscopy)

A special method of controlled illumination ideally suited to observing thin, transparent objects where structural details vary only slightly in thickness or refractive index. This can also be applied to the examination of opaque materials to determine surface elevation changes.

Phase Diagram

A graphical representation of the temperature and composition limits of phase fields in an alloy or ceramic system as they actually exist under the specific conditions of heating or cooling. A phase diagram may be an equilibrium diagram, an approximation to an equilibrium diagram, or a representation of metastable conditions or phases. Synonymous with constitution diagram. Compare with *equilibrium diagram*.

Phase Rule

(1) The maximum number of phases (P) that may exist at equilibrium is two, plus the number of components (C) in the mixture, minus the number of degrees of freedom (F). (2) (Gibb's) rule—for the general case and equilibrium:

$$P + F = C + E$$

where

P is the number of phases present

F is the number of degrees of freedom or variants

C is the number of components, that is, stable chemical substances

E is the number of environmental factors, that is, two—temperature and pressure

In the case of metal reactions, the consequences of varying pressure are insignificant and can be ignored leaving temperature as the only environmental factor so the equation becomes

$$P + F = C + 1.$$

In this case, the components are the pure metals or other elements that comprise the alloy.

Phase Separation

The formation of a second liquid portion from a previously homogenous liquid over time.

Phase-Change Lubrication

See *melt lubrication*.

Phenol

Phenol is the simplest member of a class of organic compounds possessing a hydroxyl group attached to a benzene ring or to a more complex aromatic ring system.

Also known as carboic acid or monohydroxybenzene, phenol is a colorless to white crystalline material of sweet odor, having the composition $\text{C}_6\text{H}_5\text{OH}$, obtained from the distillation of coal tar and as a by-product of coke ovens.

Phenol has broad biocidal properties, and dilute aqueous solutions have long been used as an antiseptic. At higher concentrations, it causes severe skin burns; it is a violent systemic poison. It is a valuable chemical raw material for the production of plastics, dyes, pharmaceuticals, syntans, and other products.

Properties

Phenol melts at about 43°C and boils at 183°C. The pure grades have melting point of 39°C, 39.5°C, and 40°C. The technical grades contain 82%–84% and 90%–92% phenol. The crystallization point is given as 40.41°C. The specific gravity is 1.066. It dissolves in most organic solvents. By melting the crystals and adding water, liquid phenol is produced, which remains liquid at ordinary temperatures. Phenol has the unusual property of penetrating living tissues and forming a valuable antiseptic. It is also used industrially in cutting oils and compounds and in tanneries. The value of other disinfectants and antiseptics is usually measured by comparison with phenol.

Uses and Derivatives

Phenol is one of the most versatile industrial organic chemicals. It is the starting point for many diverse products used in the home and industry. A partial list includes nylon, epoxy resins, surface active agents, synthetic detergents, plasticizers, antioxidants, lube oil additives, phenolic resins (with formaldehyde, furfural, and so on), cyclohexanol, adipic acid, polyurethanes, aspirin, dyes, wood preservatives, herbicides, drugs, fungicides, gasoline additives, inhibitors, explosives, and pesticides.

Phenol Formaldehyde Resin

This is a synthetic resin, commonly known as phenolic, made by the reaction of phenol and formaldehyde, and employed as a molding material for making of mechanical and electrical parts. It was the earliest type of hard, thermoset synthetic resins, and its favorable combination of strength, chemical resistance, electrical properties, glossy finish, and nonstrategic abundance of low-cost raw materials has maintained the resin, with its many modifications and variations, as one of the most widely employed groups of plastics for a variety of products. The resins are also used for laminating, coatings, and casting resins.

Phenolic resins are used most extensively as thermosetting plastic materials, as there are only a few uses as thermoplastics. The polymer is composed of carbon, hydrogen, oxygen, and sometimes nitrogen. Its molecular weight varies from a very low value during its early state of formation to almost infinity in its final state of cure. The chemical configuration, in the thermoset state, is usually represented by a 3D network in which the phenolic nuclei are linked by methylene groups. The completely cross-linked network requires three methylene groups to two phenolic groups. A lesser degree of cross-linking is attainable either by varying the proportions of the ingredients or by blocking some of the reactive positions of the phenolic nucleus by other groups, such as methyl and butyl. Reactivity can be enhanced by increasing the hydroxyl groups on the phenolic nuclei, for example, by the use of resorcinol.

Characteristics

The outstanding characteristics of phenolics are good electrical properties, very rigid set, good tensile strength, excellent heat resistance, good rigidity at elevated temperature, good aging properties, and also good resistance to water, organic solvents, weak bases, and weak acids. All these characteristics are coupled with relatively low-cost.

Phenolics are used in applications that differ widely in nature. For example, wood is impregnated to make “impreg” and “com-preg”; paper is treated to make battery separators and oil and air filters; specific chemical radicals can be added to the molecule to make an ion-exchange material. Phenolics are also widely used in protective coating.

The hundreds of different phenolic molding compounds can be divided into six groups on the basis of major performance characteristics. General-purpose phenolics are low-cost compounds with fillers such as wood flour and flock and are formulated for noncritical functional requirements. They provide a balance of moderately good mechanical and electrical properties and are generally suitable in temperatures up to 149°C. Impact-resistant grades are higher in cost. They are designed for use in electrical and structural components subject to impact loads. The fillers are usually paper, chopped fabric, or glass fibers. Electrical grades, with mineral fillers, have high electrical resistivity plus good arc resistance, and they retain their resistivity under high-temperature and high-humidity conditions. Heat-resistant grades are usually mineral- or glass-filled compounds that retain their mechanical properties and the 190°C–260°C temperature range.

Special-purpose grades are formulated for service applications requiring exceptional resistance to chemicals or water, or combinations of conditions such as impact loading and a chemical environment. The chemical-resistant grades, for example, are inert to most common solvents and weak acids, and their alkali resistance is good. Nonbleeding grades are compounded specially for use in container closures and for cosmetic cases.

Fillers Proper balance of fillers is important, because too large a quantity may produce brittleness. Organic fillers absorb the resin and tend to brittleness and reduce flexural strength, although organic fibers and fabrics generally give high impact strength. Wood flour is the most usual filler for general-service products, but prepared compounds may have mineral powders, mica, asbestos, organic fibers, macerated fabrics, or mixtures of organic and mineral materials. Bakelite was the original name for phenol plastics, but trade names now usually cover a range of different plastics, and the types and grades are designated by numbers.

The specific gravity of filled phenol plastics may be as high as 1.70. The natural color is amber, and, as the resin tends to discolor, it is usually pigmented with dark colors. Normal phenol resin cures to single-carbon methylene groups between the phenolic groups, and the molded part tends to be brittle. Thus, many of the innumerable variations of phenol are now used to produce the resins, and modern phenol resins may also be blended or cross-linked with other resins to give higher mechanical and electrical characteristics. Furfural is frequently blended with the formaldehyde to give better flow, lower specific gravity, and reduced cost. The alkylated phenols give higher physical properties.

Phenol resins may also be cast and then hardened by heating. The cast resins usually have a higher percentage of formaldehyde and do not have fillers. They are poured in syrupy state in lead molds and hardened in a slow oven.

Some of the uses for phenolic resins are for making precisely molded articles, such as telephone parts, for manufacturing strong and durable laminated boards, or for impregnating fabrics, wood, or paper. Phenolic resins are also widely used as adhesives, as the binder for grinding wheels, as thermal insulation panels, as ion-exchange resins, and in paints and varnishes.

Molding Compounds The largest single use for phenolic resins is in molding compounds. To make these products, either one- or

P

two-stage resins are compounded with fillers, lubricants, dyes, plasticizers, etc. Wood flour is used as an inexpensive reinforcing agent in the general-purpose type of compounds. Cotton flock, chopped fabric, and sisal and glass fibers are used to improve strength characteristics; mineral fillers such as asbestos and mica are used where improvements in dimensional stability, heat resistance, or electrical properties are desired. The compounds are usually produced in granular, macerated, or nodular forms, depending on the type of filler used. Since the color of the base resin is not stable to light, molding compounds are commonly produced only in dark colors such as black and brown.

Molding compounds are usually processed in hardened steel molds, and molds can be designed to operate using the compression, transfer, or plunger-molding techniques, depending on the design of the article to be fabricated. Molded parts are drilled, tapped, or machined.

About one-third of all phenolic resins produced is processed into parts by molding. Compression and transfer molding are the principal processes used, but they can also be extruded and injection molded.

Molded phenolic parts are used in bottle caps, automotive ignition and engine components, electrical wiring devices, washing machine agitators, pump impellers, electronic tubes and components, utensil handles, and a multitude of other products.

Adhesives The thermosetting nature and good water- and fungus-resistant qualities of phenolic resins make them ideal for adhesive applications. Almost all exterior-grade plywood is phenolic resin bonded. This constitutes the second largest market for phenolics. The essential ingredient in many metal-to-metal and metal-to-plastic adhesives is a phenolic resin. One-stage phenol formaldehyde resins are used predominantly for hot-pressed plywood. Special resorcinol-formaldehyde resins curing at room temperature are employed for fabricating laminated timber.

Laminates The third largest use for phenolic resins is in the manufacture of laminated materials. Many variations of paper, from cheap kraft to high-quality alpha cellulose, in addition to asbestos, cotton, linen, nylon, and glass fabrics are most commonly used for reinforcing filler sheets. The laminate is formed by combining, under a temperature of 177°C and a pressure of 3.4–14 MPa, multiple layers of the various reinforcing sheet, after saturation with phenolic resin, generally of the one-stage type dissolved in alcohol.

Paper laminates are used most extensively in the electrical and decorative fields. A large number of the laminate for the electrical industry are of the punching grade, making it possible to fabricate all kinds of small parts in a punch press. The laminate used for decorative purposes usually contains a surface sheet of melamine resin-treated paper for providing unlimited color or design configurations. Other fillers are used for special applications where superior dimensional stability, or water, fire, or chemical resistance, or extra strength is required.

Casting Resins

Plastic parts can also be manufactured by pouring resin into molds and heat-curing without pressure. Two basic grades of casting resins are manufactured commercially. Both are of the one-stage type and are cured under neutral to strongly acidic conditions depending on the application. The first grade is manufactured for its variegated color and artistic possibilities and is used primarily in the cutlery and decorative field. Since this type of cast material is noted for ease of machining, it is well adapted for small production runs or where machined prototypes are desired.

The second grade of casting resins includes all those modified by fillers and reinforcing agents. Designed primarily to have low-shrinkage characteristics during cure, they are usually set with a strong acid catalyst to obtain a low-temperature set. Uses include containers, jigs, fixtures, and metal-forming dies.

Bonding Agents Phenolic resins are noted for their excellent bond strength characteristics under elevated temperature conditions and thus are used in such applications as thermal and acoustical insulation, grinding wheels, coated abrasives, brake linings, and clutch facings. Glass wool insulation is manufactured by spraying water-soluble one-stage resins on the glass fibers as they are formed. Heat given off by the fibers as they cool is sufficient to set the resin. Where organic fibers are used, finely pulverized, one-stage resins are distributed between the fibers, either by a mixing or a dusting operation, followed by an oven treatment.

Grinding wheels bonded with phenolic resin are commonly known as resinoid-bonded wheels. By combining a liquid one-stage resin and a powdered two-stage resin, the material can be evenly distributed with abrasive grit and fillers so that the mixture can be pressed into wheels and baked in ovens. Some wheels are also hot-pressed and cured directly in a press. Resinoid-bonded wheels are used primarily where the application requires a bond of exceptional strength such as in cutoff and snagging wheels.

Coated adhesives are manufactured by bonding abrasive grit to paper, fabric, or fiberboard by means of phenolic resins of the liquid one-stage type. Sander disks and belts are common applications.

Brake linings and clutch facings are made by bonding asbestos, fillers, metal shavings, and friction modifiers with phenolic resin, usually performed by a mixing, forming, and baking operation. Most resins for these applications are specially formulated, but simple two-stage resins are sometimes used. Formulation for each friction lining or clutch face must be determined carefully. Wood composition products of all descriptions are manufactured by hot-pressing sawdust, wood chips, or wood flour containing 8%–20% resin. Two-stage resins are most frequently used in composition boards. One-stage resins are employed for special applications where the yellow color or the slight ammonia odor of two-stage resins is undesirable.

Foundry Use A relatively new application holding great promise for phenolic resins is in the shell mold process for the foundry industry. The basic principle involves binding sand grains with resin. The process is equally well adapted to making cores and is satisfactory for practically all metals, including magnesium and chrome alloys.

The process has many intriguing possibilities. Molds thus made can be reproduced in exact composition, detail, and size; they are rigid and, having no affinity for water, can be racked and stored indefinitely, with or without cores. Castings from these molds have excellent surface finish and detail and can be held too close to dimensional tolerances. The process can be completely mechanized, yields more castings per ton of melt than sand casting, simplifies cleaning of castings, minimizes problems with sand control and handling, and is a relatively clean operation. It is revolutionizing the foundry industry.

Consumption of resin in the foundry industry has grown rapidly, and conceivably this could become the largest single outlet for phenolics. However, markets for phenolic resins and plywood adhesive, insulation, and wood composition board applications have also expanded.

Phenoxy Resin

A high-molecular-weight thermoplastic polyester resin (polyhydroxy ether) based on bisphenol A and epichlorohydrin. The material is

available in grades suitable for injection molding and extrusion and for applications such as coatings and adhesives.

Phenylsilane Resins

Thermosetting copolymers of silicone and phenolic resins. Furnished in solution form.

Phosgene

The common name for carbonyl chloride, COCl_2 , a colorless, poisonous gas made by the action of chlorine on carbon monoxide. It was used as a poison war gas. But it is now used in the manufacture of metal chlorides and anhydrides, pharmaceuticals, perfumes, isocyanate resins, and for blending in synthetic rubbers. It liquefies at 7.6°C and solidifies at -118°C . It is decomposed by water. When chloroform is exposed to light and air, it decomposes into phosgene. One part in 10,000 parts of air is a toxic poison, causing pulmonary edema. For chemical warfare, it is compressed into a liquid in shells.

Because of its toxicity, most phosgene is produced and employed immediately in captive applications. The biggest use of the material is for toluene diisocyanate, which is then reacted into polyurethane resins for foams, elastomers, and coatings. About 0.9 metric ton of phosgene is consumed to make a metric ton of polymethylene polyphenylisocyanate, also used for making polyurethane resins for rigid foams. Polycarbonate manufacturers require 0.42 metric ton phosgene per ton of product resin. Polycarbonate is used for making break-resistant housings, signs, glazings, and electrical tools. Phosgene also is a reactant for isocyanates that are used in pesticides and di- and polyisocyanates in adhesives, coatings, and elastomers.

Phosphate Conversion Coatings

Phosphate coatings have been used commercially for approximately 50 years. They are used on iron, steel, zinc, and aluminum surfaces to increase corrosion protection, provide a base for paint, reduce wear on bearing parts, and aid in the cold forming and extrusion of metals.

Phosphate coatings are formed by chemically reacting a clean metal surface with an aqueous solution of a soluble metal phosphate of zinc, iron, or manganese, accelerating agents, and free phosphoric acid. For example, when steel is treated, the surface is converted into a crystalline coating consisting of secondary and tertiary phosphates, adherent to and integral with the base metal.

The performance of a phosphate coating depends largely on the unique properties of the coating, which is integrally bound to the base metal and acts as a nonmetallic, adsorptive layer to hold a subsequent finish of oil or wax, paint, or lubricant. Heavy phosphate coatings are normally used in conjunction with an oil or wax for corrosion resistance. The combination of the coating with the oil film gives a synergistic effect, which affords much greater protection than that obtained by the sum of the two taken separately. The stable, nonmetallic, nonreactive phosphate coating provides an excellent base for paint. It is chemically combined with the metal surface, which results in increased adsorption of paint and materially reduces electrochemical corrosion normally occurring between the paint film and the metal.

Oil-absorptive phosphate coatings are useful in holding and maintaining a continuous oil film between metal-to-metal moving parts. They also permit rapid break-in of new bearing surfaces. Even after the coatings have been worn away, the controlled etched condition

of the metal surface continues to hold the oil film between the moving parts. The ability of a well-anchored coating to hold a soap or oil-type lubricant is used in the cold forming and drawing of metals.

Processes

Most phosphate coatings are formed from heated solutions following a hot cleaning cycle. Effective coatings, both zinc phosphate and the iron phosphate types, are now produced by the relatively cold system with up to 70% savings in heating costs.

All steel must be thoroughly cleaned prior to phosphate coating to remove grease, oil, rust, and undesirable soils on the steel surface, which prevent or alter the formation of a satisfactory phosphate coating and interfere with paint adhesion. The cleaner used to remove oily soil prior to the formation of the zinc phosphate coating is a light-duty, mildly alkaline material especially formulated to function effectively at low temperature. The cleaner that is best suited for use in connection with low-temperature iron phosphate coating process may be either a light-duty, low-foaming, mildly acidic, or mildly alkaline cleaner, depending upon the conditions of operation.

Proper formulation of the phosphating solutions allows the coatings to form rapidly at low temperature on the cleaned steel surface. Simple, on-the-job, chemical controls enable the operator to adjust the addition of coating chemicals to the requirements of the steel being treated.

Following the coating operation, a cold water rinse is used to remove excess coating chemicals. The flow of water through the rinse is regulated with the rate of production so that contamination of the main body of the rinse is minimized. An acidified rinse containing hexavalent chromium compounds follows the water rinse. This lapse has a specific effect of enhancing the corrosion resistance of the coating. An oven dry-off to remove surface moisture completes the process.

Typical products being treated by the cold phosphate system are automotive body and sheet-metal parts, refrigerator cabinets, office furniture, lighting fixtures, commercial air conditioners, home heating equipment, home laundries, kitchen cabinets, desk and filing cabinets, steel drums, and window sash.

There are advantages of the cold phosphate system over conventional methods that require higher-temperature operation:

1. Direct heat savings—up to 70%
2. Less heat-up time
3. Less maintenance due to decreased load on heating coils, steam traps, etc.
4. Reduce downtime (maintenance personnel can enter the units immediately after shutdown to make adjustments or repairs)
5. Increased worker comfort near the installation
6. Reduced use of water through decreased evaporation
7. Elimination of exhaust fans

Applications

Phosphate conversion coatings have a wide range of application. Several examples follow.

Base for Plastisol Coatings

The domestic appliance industry has pointed toward the use of plastisol (polyvinyl chloride) coatings as a replacement for more costly porcelain enamel. During this period, several major manufacturers of domestic dishwashers have standardized on plastisol films for coating tubs, lids, dish racks, etc.

P

The metal preparation method meeting this requirement was a zinc phosphate coating system. The fabricated parts are cleaned in a conditioned cleaner, phosphated, and rinsed thoroughly. The rinse procedure includes an acidified chromic-phosphoric acid rinse followed by a closely controlled deionized water rinse and thorough drying to remove surface moisture. This treatment produces a continuous, uniform, fine-grained coating of approximately 150–250 mg of zinc phosphate coating per square foot of surface area treated.

After the steel has been zinc phosphate coated and especially formulated, a primer is applied to a very thin and closely controlled film build and followed by the subsequent application of 12–15 mils of plastisol with an intermediate and final baking operation.

Bond for Vinyl Coatings

Vinyl films of 5–15 mils thickness are applied to both steel and aluminum sheets by lamination of calendered and decorated films or by spray or roller coating. For the vinyl laminate as with the plastisol application, the base metal must be chemically treated to provide the necessary bond for laminate to metal surface. A controlled, accelerated iron phosphate treatment followed by an acidified chromate rinse has proved to be best for the preparation of steel for vinyl lamination to sheet or coil on a continuous line. This method is now being used by several fabricators and rollers of steel.

Aluminum can also be finished with vinyl laminates and plastisols. Chromate conversion coatings of the “gold” oxide type provide excellent adhesion of the vinyl film as well as excellent corrosion resistance on the unprotected surface.

Metal preparation for both steel and aluminum is usually done by spray application in five-stage equipment in the following sequence:

1. Alkali claim—30 s (smutty steel may require brush scrubbing)
2. Water rinse—10 s
3. Phosphate coating—10 s
4. Water rinse—5 s
5. Acidified chromate rinse—6 s

The same sequence and time cycles are used for aluminum except that an appropriate chromate conversion coating solution is in stage 3. Consequently, installations have been engineered to prepare both steel and aluminum for subsequent application of vinyl laminates by providing interchangeable coating solution tanks at that stage, thereby providing efficient and versatile “in-line” operation for this new decorative treatment.

Bolt Making

Phosphate coatings are also finding wide acceptance in the fastener industry as applied to rod to facilitate the forming of bolts. The coating is produced from a dilute, especially accelerated, zinc acid phosphate solution that reacts chemically with the surface of the rod to form an insoluble nonmetallic phosphate coating integral with the surface of the rod. The coating forms a porous bond to carry the extruding and heading lubricant and prevent metal-to-metal contact and subsequent heading operations. The result is longer tool life, increased percentage of reduction, and improved surface appearance of the finished product.

The methods of application vary from the conventional pickle-house immersion method to the in-line strand processes. In the immersion method, the coils of scaled rods are dipped in the treating solutions in the following sequence of operations:

1. Acid pickle—10 min to 2.5 h
2. Water rinse—cold, overflowing, or spray

3. Hot water rinse
4. Phosphate coating—5–15 min, 71°C–93°C
5. Cold water rinse
6. Neutralizing rinse—line
7. Soap dip
8. Bake dry

It has been found that a dip in a high-strength soap solution improves die life and reduces knockout pressures. The soap solution follows the neutralizing rinse, or in some instances, it is combined with the neutralizing rinse.

The in-line strand process eliminates intermediate handling from scaled rod to drawn wire and the necessity of acid disposal. The coils are handled continuously. Line speeds up to ~300 million m/s are required with this process so that the phosphate solution must deposit the desired heavy coating in about 15 s.

Even during this extremely short processing time, a line speed up to ~300 million m/s requires a special coating tank. Compact prerinse and neutralizing rinse stages are incorporated in this unit from which it is possible to obtain better than 750 mg/ft² of coating and 15 s by use of specially formulated phosphate solutions adapted to strand processing.

Wire produced by the strand method of processing produces wire superior in quality to that produced by conventional cleaning and drawing methods and does so at lower cost. As a consequence of the better quality, phosphate-base-lubricated material will produce close tolerance bolts with full heads and sharp shoulders.

Wire Drawing

Phosphate coatings are also gaining acceptance as a lubricant carrier in the wire industry to permit increased drawing speeds and prolonged die life. This is particularly true in connection with both the dry and wet drawing of high carbon wire. Other advantages that the zinc phosphate coatings afford to the wire industry are increased corrosion resistance after drawing and closer dimensional tolerances. Improved dimensional tolerance is a major advantage in forming springs from spring wire.

The zinc phosphate coating may be applied by immersion in the conventional pickle house installation, or by the newly developed fast coating, continuous strand method. The continuous strand method fits in well with fast, in-line travel of the wire. This adaptability and the lower labor costs involved warrant the recommendation of strand phosphate lines in wire processing.

Extrusion

Another important development is the use of zinc phosphate coatings as an aid in the rapidly developing field of cold extrusion of steel and aluminum. In this application, the phosphate coating solution is formulated to deposit a considerably heavier zinc phosphate coating than heretofore mentioned. The coating is then chemically reacted with a soap-base lubricant to form a water-insoluble lubricating film.

The use of the zinc phosphate coating is considered a basic requirement in the cold extrusion field where the pressure exerted by the tools on the steel being formed may be in excess of 2040 MPa. The phosphate and lubricant coating withstands the high unit pressure and temperatures developed in this type of cold forming. At the same time, it maintains the required separating film between the tools and workpiece being extruded to prevent scoring, galling, and tool breakage. A specially formulated phosphate coating solution produces a zinc phosphate coating on aluminum and is gaining wide acceptance as an aid in the cold extrusion of the heat-treatable alloys of this metal.

Phosphate Glass

A glass in which the essential glass former in phosphorus pentoxide (P_2O_5) instead of silica. Also used in *glass-ceramics* and *glass tableware*.

Phosphating

(1) Forming an adherent phosphate coating on a metal by immersion in a suitable aqueous phosphate solution. Also called *phosphatizing*.
(2) The production of a thin conversion coating of metal phosphate on the surface of, usually, steel. The coating offers useful corrosion resistance on finished components and improves lubrication/friction characteristics of material requiring further cold work such as drawing. See also *conversion coating*.

Phosphor

A substance capable of luminescence, that is, absorbing energy such as x-rays, ultraviolet radiation, electrons, or alpha particles, and emitting a portion of that energy in the visible or near-visible region. If emission ceases within 10^{-4} s after excitation, the phosphor is fluorescent; if it persists, it is called phosphorescent. See also *fluorescence* and *phosphorescence*.

Phosphor Bronze

This, a copper-base alloy with low phosphorus content, originally called steel bronze, was 92/8 bronze deoxidized with phosphorus and cast in an iron mold. It is now any bronze deoxidized by the addition of phosphorus to the molten metal. It may or may not contain residual phosphorus in the final state. Ordinary bronze frequently contains cuprous oxide formed by the oxidation of the copper during fusion. By the addition of phosphorus, a partial reducing agent, a complete reduction of the oxide takes place. Phosphor bronzes have excellent mechanical and cold-working properties and low coefficient of friction, making them suitable for springs, diaphragms, bearing plates, and fasteners. In some environments, such as saltwater, they are superior to copper.

At present, there are 18 standard wrought phosphor bronzes, designated C50100–C54800. Tin, which ranges from as much as 0.8%–1% depending on the alloy, is the principal alloying element, although leaded alloys may contain as much lead (e.g., 4%–6%) as tin. Phosphate content is typically on the order of 0.1%–0.35%, zinc 0%–0.3% (1.5%–4.5% in C 54400), iron 0%–0.1%, and lead 0%–0.05% (0.8%–6% in leaded alloys). The principal alloys were formally known by letter designation representing nominal tin content: phosphor bronze A, 5% tin (C51000); phosphor bronze B, 4.75% tin (C53200); phosphor bronze C, 8% tin (C52 100); phosphor bronze D, 10% tin (C52400); and phosphor bronze E, 1.25% tin (C50500). Phosphor bronze E, almost 99% copper, is one of the leanest of these bronzes in the way of alloying ingredients and is used for electrical contacts, pole-line hardware, and flexible tubing. Its electrical conductivity is about half that of copper, and it is readily formed, soldered, brazed, and flash-welded. Thin flat products have tensile yield strengths ranging from about 83 MPa in the annealed condition to 517 MPa in the extra spring temper. More highly alloyed C54400 (4% tin, 4% lead, and 3% zinc, nominally) is about 1/5 as electrically conductive as copper and has good forming characteristics and 80% of the machinability of C36000, a free-machining brass. Its ultimate tensile strength ranges from about 331 MPa in the annealed condition to 690 MPa in the extra spring temper. Its uses include bearings, bushings, gear shafts, valve components, and screw-machined products. See *bearing bronzes*.

Phosphor Copper

An alloy of phosphorus and copper, phosphor copper was used instead of pure phosphorus for deoxidizing brass and bronze and for adding phosphorus in making phosphor bronze. It comes in 5%, 10%, and 15% grades and is added directly to the molten metal. It serves as a powerful deoxidizer, and the phosphorus also hardens the bronze. Even slight additions of phosphorus to copper or bronze increase fatigue strength. Phosphor copper is made by forcing cakes of phosphorus into molten copper and holding until the reaction ceases. Phosphorus is soluble in copper up to 8.27%, forming Cu_3P , which has a melting point of about 707°C. A 10% phosphor copper melts at 850°C and a 15% at about 1022°C. Alloys richer than 15% are unstable. Phosphor copper is marketed in notched slabs or in shot.

Phosphor tin is a master alloy of tin and phosphorus used for adding to molten bronze in the making of phosphor bronze. It usually contains up to 5% phosphorus and should not contain lead. It has an appearance like antimony, with large glittering crystals, and is marketed in slabs.

Phosphorescence

A type of photoluminescence in which the time period between absorption and reemission of light is relatively long (of the order of 10^{-4} to 10 s or longer). See also *photoluminescence*. Contrast with *fluorescence*.

Phosphoric Acid

Also known as orthophosphoric acid, phosphoric acid is colorless, superbly liquid of the composition H_3PO_4 used for pickling and rust-proofing metals, for the manufacture of phosphates, pyrotechnics, and fertilizers, as a latex coagulant, as a textile mordant, as an acidulating agent in jellies and beverages, and as a clarifying agent in sugar syrup. The specific gravity is 1.65 and melting point 73.6°C, and it is soluble in water. The usual grades are 90%, 85%, and 75%, technical 50%, and dilute 10%. As a cleanser for metals, phosphoric acid produces a light edge on steel, aluminum, or zinc, which aids paint adhesion. *Deoxidine* is a phosphoric acid cleanser for metals. *Nielite D* is a phosphoric acid with a rust inhibitor, used as a non-fuming pickling acid for steel. *Albrite* is available in 75%, 80%, and 85% concentrations in food and electronic grades, both high-purity specifications. *DAB* and *Phosbrite* are called bright dip grades, for cleaning applications. Phosphoric anhydride, or phosphorus pentoxide, P_2O_5 , is a white, water-soluble powder used as a dehydrating agent and also as an opalizer for glass. It is also used as a catalyst in asphalt coatings to prevent softening at elevated temperatures and brittleness at low temperatures.

Phosphorus

Phosphorus, a chemical element, symbol P, forms the basis of a very large number of compounds; the most important class is phosphates. For every form of life, phosphates play an essential role in all energy-transfer processes such as metabolism, photosynthesis, nerve function, and muscle action. The nucleic acids that, among other things, make up the hereditary material (the chromosomes) are phosphates, as are a number of coenzymes. Animal skeletons consist of a calcium phosphate.

Uses

About 90% of the total phosphorus (in all of its chemical forms) used in the United States goes into fertilizers.

P

Commercial phosphorus is obtained from phosphate rock by reduction in the electric furnace with carbon or from bones by burning and treating with sulfuric acid. Phosphate rock occurs in the form of land pebbles and as hard rock.

The superphosphate used for fertilizers is made by treating phosphate minerals with concentrated sulfuric acid. It is not a simple compound, but may be a mixture of calcium acid phosphate, CaHPO_4 , and calcium sulfate. Nitrophosphate for fertilizer is made by acidulating phosphate rock with a mixture of nitric and phosphoric acids or with nitric acid and then ammoniation and addition of potassium or ammonium sulfate.

Other important uses are as binders for detergents, nutrient supplements for animal feeds, water softeners, additives for foods and pharmaceuticals, coating agents for metal-surface treatment, additives and metallurgy, plasticizers, insecticides, and additives for petroleum products. Except for the last four items, these uses involve phosphates.

Sodium tripolyphosphate is the major compound used in building synthetic detergents to achieve improved cleaning, primarily by dispersing inorganic soil and softening the water. The average phosphate-containing household detergent produced in the United States for washing clothes consists of about 40% by weight of sodium tripolyphosphate, $\text{Na}_5\text{P}_3\text{O}_{10}$. This compound is used extensively in water softening, as are other members of the homologous series of chain phosphates. The large-volume usage of phosphates in detergents has led to unwanted growth of algae in inland waters (lakes and rivers) into which the dirty dishwasher discharges are disposed. As a result of this fertilizing action, phosphates are considered water pollutants in those areas where such discharges occur, and in some areas, phosphates have been eliminated from detergents by law. For reasonably fast-flowing rivers that discharge directly into the ocean, phosphates are not a problem.

An interesting water-softening application is found in "threshold treatment" in which tiny traces of a chain phosphate (much less than would be used in sequestering) are used to prevent the formation of pipe scale from hard waters. The application is related to the dispersing action of the phosphates, because traces of phosphate absorb on the growing surface of the pipe scale as it begins to form, and this inhibits its further growth.

A major pharmaceutical use of phosphates is in toothpastes, in which dicalcium phosphate is the most popular polishing agent. Monocalcium phosphate and sodium acid pyrophosphate, $\text{Na}_2\text{H}_2\text{P}_2\text{O}_7$ (the pyrophosphate is the second member of the phosphate family) are employed as leavening agents in cake mixes, refrigerated biscuits, self-rising flour, and baking powder.

Automobile bodies, for example, are generally phosphatized before they are painted to prevent rusting in use. Orthophosphate esters find wide use as plasticizers that have flameproofing properties and as gasoline and oil additives.

The phosphorus compound of major biological importance is adenosine triphosphate, which is an ester of the salt sodium triphosphate, widely employed in detergents and water-softening compounds. Practically, every reaction in metabolism and photosynthesis involves the hydrolysis of this triphosphate to its pyrophosphate derivative, called adenosine diphosphate.

Phosphorus is an essential element in the human body; a normal person has more than a pound of it in the system, but it can be taken into the system only in certain compounds. Nerve gases used in chemical warfare contain phosphorus, which combines with and inactivates the cholinesterase enzyme of the brain. This enzyme controls the supply of the hormone that transmits nerve impulses, and when it is inactivated, the excess hormone causes paralysis of the nerves and cuts off breathing. Organic phosphates are widely

used in food, textile, and chemical industries. Other phosphates are used as a plasticizer in plastics and as an antifoaming agent in paper coatings and in textile sizings. They are also employed for scale and corrosion control, ore flotation, pigment dispersion, and detergents.

Flour and other foodstuffs are fortified with ferric phosphate, $\text{FePO}_4 \cdot 2\text{H}_2\text{O}$. Iron phosphate is used as an extender in paints. Tricalcium phosphate, $\text{Ca}_3(\text{PO}_4)_2$, is used as an anticaking agent in salt, sugar, and other food products and to provide a source of phosphorus. The tricalcium phosphate, used in toothpastes as a polishing agent and to reduce the staining of chlorophyll, is a fine white powder. Dicalcium phosphate, used in animal feeds, is precipitated from the bones used for making gelatin, but is also made by treating lime with phosphoric acid made from phosphate rock. Diammonium phosphate, $(\text{NH}_4)_2\text{HPO}_4$, is a mildly alkaline, white crystalline powder used in ammoniated dentifrices, for pH control in bakery products, for making phosphors, for the prevention of afterglow in matches, and for flameproofing paper.

Forms

There are two common forms of phosphorus, yellow and red. The former, also called white phosphorus, P_4 , is a light-yellow waxlike solid, phosphorescent in the dark, and exceedingly poisonous. Its specific gravity is 1.83 and it melts at 44°C . It is used for smoke-screens in warfare and for rat poisons and matches. Yellow phosphorus is produced directly from phosphorus rock in the electric furnace. It is cast to cakes of 0.45–1.36 kg each. Red phosphorus is a reddish-brown amorphous powder, with a specific gravity of 2.20 and a melting point of 725°C . Red phosphorus is made by holding white phosphorus at its boiling point for several hours in a reaction vessel. Both forms ignite easily. Amorphous phosphorus, or crystalline black phosphorus, is made by heating white phosphorus for extended periods. It resembles graphite and is less reactive than the red or white forms, which can ignite spontaneously in air. Black phosphorus is made by this process. Phosphorus sulfide, P_4S_3 , may be used instead of white phosphorus in making matches. Phosphorus pentasulfide, P_2S_5 , is a canary-yellow powder with a specific gravity of 1.30 or solid with a specific gravity of 2.0, containing 27.8% phosphorus, used in making oil additives and insecticides. It is decomposed by water.

Phosphorized Copper

General term applied to copper deoxidized with phosphorus. The most commonly used deoxidized copper. The small amount of residual phosphorus, typically 0.02%, seriously reduces electric conductivity.

Phosphorus Banding

See *ghost banding*.

Photoelastic Modeling/Stress Analysis

A technique in which a model of some component is formed in a suitable plastic and deformed while being viewed under polarized light. The bright and dark areas that are produced in the plastic by interference effects indicate the state and direction of stresses. It is possible to stress the model, which can be, for example, a complex pressure vessel, while warm and then allow it to cool under stress to "freeze in" the strain. The model of sections cut from it may then be examined at leisure.

Photoelasticity

An optical method for evaluating the magnitude and distribution of stresses, using a transparent model of a part or a thick film of photoelastic material bonded to a real part.

Photoelectric Effect

The liberation of electrons by electromagnetic radiation incident on a substance.

Photoelectric Electron Multiplier Tube

See *photomultiplier tube*.

Photographic Materials

These are the light-sensitive recording materials of photography, that is, photographic films, plates, and papers. They consist primarily of a support of plastic sheeting, glass, or paper, respectively, and a thin, light-sensitive layer, commonly called the emulsion, in which the image will be formed and stored. The material will usually embody additional layers to enhance its photographic or physical properties.

Supports

Film support, for many years made mostly of flammable cellulose nitrate, is now exclusively made of slow-burning "safety" materials, usually cellulose triacetate or polyester terephthalate, which are manufactured to provide thin, flexible, transparent, colorless, optically uniform, tear-resistant sheeting. Polyester supports, which offer added advantages of toughness and dimensional stability, are widely used for films intended for technical applications. Film supports usually range in thickness from 0.06 to 0.23 mm and iron maiden rolls up to 1.5 in. wide and 1800 m long.

Glass is the predominant substrate for photographic plates, although methacrylate sheet, fused quartz, and other rigid material are sometimes used. Plate supports are selected for optical clarity and flatness. Thickness, ranging usually from 1 to 6 mm, is increased with plate size as needed to resist breakage and retain flatness. The edges of some plates are especially ground to facilitate precise registration.

Photographic paper is made from bleached wood pulp of high α -cellulose content, free from ground wood and chemical impurities. It is often coated with a suspension of barium sulfate in gelatin for improved reflectance and may be calendered for high smoothness. Fluorescent brighteners may be added to increase the appearance of whiteness. Many paper supports are coated on both sides with water-repellent synthetic polymers to preclude wetting of the paper fibers during processing. This treatment hastens drying after processing and provides improved dimensional stability and flatness.

Emulsions

Most emulsions are basically a suspension of silver halide crystals in gelatin. The crystals, ranging in size from 2.0 to less than 0.05 μm , are formed by precipitation by mixing a solution of silver nitrate with a solution containing one or more soluble halides in the presence of a protective colloid. The salts used in these emulsions are chlorides, bromides, and iodides. During manufacture, the emulsion is ripened to control crystal size and structure. Chemicals are added in small but significant amounts to control speed, image tone, contrast, spectral sensitivity, keeping the qualities, fog, and hardness; to facilitate uniform coating; and, in the case of color films and papers,

to participate in the eventual formation of dye instead of metallic silver images upon development. The gelatin, sometimes modified by the addition of synthetic polymers, is more than a single vehicle for the silver halide crystals. It interacts with the silver halide crystals during manufacture, exposure, and processing and contributes to the stability of the latent image.

After being coated on a support, the emulsion is chilled so that it will set and then dried to a specific moisture content. Many films receive more than one high-sensitive coating, with individual layers as thin as 1.0 μm . Overall thickness of the coatings may range from 5 to 25 μm , depending on the product. Most x-ray films are sensitized on both sides, and some black-and-white films are double coated on one side. Color films and papers are coated with at least three emulsion layers and sometimes six or more plus filter and barrier layers. A thin, nonsensitized gelatin layer is commonly placed over film emulsions to protect against abrasion during handling. A thicker gelatin layer is coated on the back of most sheet films and some roll films to counteract the tendency to curl, which is caused by the effect of changes in relative humidity on the gelatin emulsion. Certain films are treated to reduce electrification by friction because static discharges can expose the emulsion. The emulsion coatings on photographic papers are generally thinner and more highly hard than those on film products.

Another class of silver-based emulsions relies on silver behenate compounds. These materials require roughly 10 times more exposure than silver halide emulsions having comparable image structure properties (resolving power, granularity); are less versatile in terms of contrast, maximum density, and spectral sensitivity; and are less stable both before exposure and after development. However, they have the distinct advantage of being processed through the application of heat (typically at 116°C–127°C) rather than a sequence of wet chemicals. Hence, products of this type are called dry silver films and papers.

Photoluminescence

Reemission of light absorbed by an atom or molecule. The light is emitted in random directions. There are two types of photoluminescence: *fluorescence* and *phosphorescence*.

Photomacrograph

A macrograph produced by photographic means.

Photometer

A device so designed that it measures the ratio of the radiant power of two electromagnetic beams.

Photomicrograph

A micrograph produced by photographic means.

Photomicrograph/Macrograph

Photographs taken with a microscope at high/low magnifications.

Photomultiplier Tube

(1) A device in which incident electromagnetic radiation creates electrons by the *photoelectric effect*. These electrons are accelerated by a series of electrodes called dynodes, with secondary emission

P

adding electrons to the stream at each dynode. (2) A light-sensitive vacuum tube with multiple electrodes providing a highly amplified electrical output.

Photon

(1) A particle representation of the electromagnetic field. The energy of the photon equals $h\nu$, where ν is the frequency of the light in hertz and h is Planck's constant. See also *Planck's constant*. (2) A quantum, that is, a single indivisible portion, of light energy.

Photopolymer

A polymer that changes characteristics when exposed to light of a given frequency.

Photoresist

(1) A radiation-sensitive material which, when properly applied to a variety of substrates and then properly exposed and developed, masks portions of the substrate with a high degree of integrity. (2) A photosensitive coating that is applied to a laminate and subsequently exposed through a photo tool (film) and developed to create a pattern that can be either plated or etched.

Photosensitive

Sensitive to light.

Phthalate Esters

The most widely used group of *plasticizers*, produced by the direct action of alcohol on phthalic anhydride. The phthalates are generally characterized by moderate cost, good stability, and good all-around properties.

Phthalic Anhydride

A white, crystalline material with a melting point of 267°F (130.8°C) soluble in water and in alcohol. It is made by oxidizing naphthalene, or it is produced from orthoxylene derived from petroleum. BASF Corp. markets the product both as flake and in the molten state. It is used in the manufacture of alkyd resins and for the production of dibutyl phthalate and other plasticizers, dyes, and many chemicals. *Chlorinated phthalic anhydride* is also used as a compounding medium in plastics. It is a white, odorless, nonhygroscopic, stable powder containing 50% chlorine. It gives higher-temperature resistance and increased ability to plastics. *Terephthalic acid* may be obtained as a by-product in the production of phthalic anhydride from petroleum. It has a long-chain alkyl group having an amide linkage on one end and a methyl ester on the other. It is used for producing *polyethylene terephthalate* and other polyesters. The esters can also be made from *dimethyl terephthalate*, a molten material but burns readily when ignited. The dust can form explosive mixtures with air. The terephthalates are useful in textile and tire cord fibers, plastic tape, and food-packaging polymers. Their sodium salt is used as a gelling agent for lubricating grease used in high temperatures up to 600°F (316°C). It forms fine *crystallites* of soft, flexible fibers in the grease.

Maleic anhydride is also a building block for L-aspartame, use for making *NutraSweet*, the aspartame synthetic sweetener.

Maleic anhydride was traditionally made from benzene, but *n*-butane has become the feedstock of choice because of its lower cost and because benzene is a carcinogen. In the United States, the transition was completed in the late 1980s. Recent uses for maleic anhydride, and *maleic acid* recovered from the catalytic oxidation of butane to maleic anhydride, are the production of chemical intermediates.

Physical Adsorption

See *physisorption*.

Physical Blowing Agent

A gas, such as a fluorocarbon, which is pumped into a mold during the forming of plastics.

Physical Crack Size (α_p)

In fracture mechanics, the distance from a reference plane to the observed crack front. This distance may represent an average of several measurements along the crack front. The reference plane depends on the specimen form, and it is normally taken to be either the boundary or a plane containing either the load line or the centerline of a specimen or plate.

Physical Etching

Development of microstructure through removal of atoms from the surface or lowering the grain-surface potential.

Physical Metallurgy

The science and technology dealing with the properties of metals and alloys and of the effects of composition, processing, and environment on those properties at an atomic and microscopical level.

Physical Objective Aperture

In electron microscopy, a metal diaphragm centrally pierced with a small hole used to limit the cone of electrons accepted by the objective lens. This improves image contrast, because highly scattered electrons are prevented from arriving at the Gaussian image plane and therefore cannot contribute to background noise.

Physical Properties

Properties of a material that are relatively insensitive to structure and can be measured without the application of force; for example, density, electrical conductivity, coefficient of thermal expansion, magnetic permeability, and lattice parameter. Does not include chemical reactivity. Compare with *mechanical properties*.

Physical Testing

Methods used to determine the entire range of a material's *physical properties*. In addition to density and thermal, electrical, and magnetic properties, physical testing methods may be used to assess simple fundamental physical properties such as color, crystalline form, and melting point.

Physical Vapor Deposition (PVD)

A coating process whereby the deposition species are transferred and deposited in the form of individual atoms or molecules. The most common PVD methods are sputtering and evaporation. Sputtering, which is the principal PVD process, involves the transport of a material from a source (target) to a substrate by means of the bombardment of the target by gas ions that have been accelerated by a high voltage. Atoms from the target are ejected by momentum transfer between the incident ions in the target. These ejected particles move across the vacuum chamber to be deposited on the substrate. Evaporation, which was the first PVD process used, involves the transfer of material to form a coating by physical means alone, essentially the vaporization. The streaming vapor is generated by melting and evaporating a coating material source bar, by an electron beam in a vacuum chamber. Because both of these methods are line-of-sight processes, it is necessary to use specially shaped targets or multiple evaporation sources and to rotate or move the substrate uniformly to expose all areas. PVD coatings are used to improve the wear, friction, and hardness properties of cutting tools and as corrosion-resistant coatings.

Physisorption

The binding of an adsorbate to the surface of a solid by forces whose energy levels approximate those of condensation. Contrast with *chemisorption*.

PI

See *polyimide*.

pi Bonding

Covalent bonding of atoms in which the atomic orbitals overlap along a plane perpendicular to the sigma bond(s) joining the nuclei of two or more atoms. See also *sigma bonding*.

pi Electron

An electron that participates in *pi bonding*.

Piano Wire

High tensile (up to about 2000 MPa, 130 tons/in.²), high carbon (about 0.9%) steel wire produced by patenting.

PIC

See *pressure impregnation-carbonization*.

Pick Count

In reinforced plastics, the number of *tows*/mm (in.) of woven fabric in both the *warp* and *fill* directions.

Pickle

The chemical removal of surface oxides (scale) and other contaminants such as dirt from iron and steel by immersion in an aqueous

acid solution. The most common pickling solutions are sulfuric and hydrochloric acids.

Pickle Embrittlement

See *pickling*.

Pickle Liquor

A spent acid-pickling bath.

Pickle Patch

A tightly adhering oxide or scale coating not properly removed during *pickling*.

Pickle Stain

Discoloration of metal due to chemical cleaning without adequate washing and drying.

Pickling

The removal of scale and other contaminants from the surface of a metal component by immersion in appropriate chemicals, commonly acids or alkalis or electrochemical reaction. It is implicit that the metal component is not significantly attacked and often inhibitors are added to achieve this. If carried out, steel, particularly of high hardness, can be charged with hydrogen from the surface reaction causing a form of hydrogen embrittlement called *pickle embrittlement* or similar terms. The hydrogen can be allowed to diffuse out by baking at about 200°C for some hours.

Pickling Acids

Acid used for pickling or cleaning castings or metal articles. The common pickling bath for iron and steel is composed of a solution of sulfuric acid and water, one part acid to 5–10 parts water being used. This acid attacks the metal and cleans it from oxides and sand by loosening them. For pickling scale from stainless steels, a 25% cold solution of hydrochloric or sulfuric acid is used, or hydrofluoric acid with the addition of anhydrous ferric sulfate is used. Hydrofluoric acid solutions are sometimes used for pickling iron castings. This acid attacks and dissolves away the sand itself. For bright-cleaning brass, a mixture of sulfuric acid and nitric acid is used. For a matte finish, the mixed acid is used with a small amount of zinc sulfate. Copper and copper alloys can be pickled with sulfuric acid to which anhydrous ferric sulfate is added to speed the action, or sodium bichromate is added to the sulfuric acid to remove red cuprous oxide stains. Brass forgings are pickled in nitric acid to bring out the color. Since all of these acids form salts rapidly by the chemical action with a metal, they must be renewed with frequent additions of fresh acid. The French pickling solution known as *framanol*, used for aluminum, is a mixture of chromium phosphate and triethanolamine. The latter emulsifies the grease and oil, and the aluminum oxide film is dissolved by the phosphoric acid, leaving the metal with a thin film of chromic oxide.

The temperature of most pickling is from 140°F to 180°F (60°C–82°C). An increase of 20°F (11°C) will double the rate of pickling. *Acid brittleness* after pickling is due to the absorption of hydrogen when the acid acts on iron and is reduced by shortening the pickling time. *Inhibitors* are chemicals added to reduce the time

P

of pickling by permitting higher temperatures and stronger solutions without hydrogen absorption. In plating baths, fluoboric acid, HBF_4 , has high throwing power and has a cleansing effect by dissolving sand and silicides from iron castings and steel surfaces. It is a colorless liquid with a specific gravity of 1.33.

Phosphoric acid is employed in a hot solution as a dip bath for steel parts to be finished to a rough or etched surface. It leaves a basic iron phosphate coating on a steel which is resistant to corrosion and gives a rough base for the finish. *Parkerized steel* is rustproof steel treated in a bath of iron and manganese phosphates. *Bonderized steel* is steel treated with phosphoric acid and a catalyst to give a rough, tough, rust-resistant base for paints. *Granodized steel* is produced with zinc phosphate.

Metals can be treated with alkaline solutions, too. Rust can be removed by caustic soda baths in which a sequestrant, such as *sodium gluconate* or *ethylenediaminetetraacetic acid*, is mixed to complex the dissolved iron and keep it from precipitating.

Pick-Off

An automatic device for removing a finished part from the press die after it has been stripped.

Pickup

(1) Transfer of metal from tools to part or from part to tools during a forming operation. (2) Small particles of oxidized metal adhering to the surface of a *mill product*. (3) Undesirable material collected or entrained during some process. Elements entering the weld metal during fusion of the parent metal.

Pickup Roll

A spreading device where the roll for picking up the adhesive runs in a reservoir of adhesive.

Picral

Picric acid in alcohol used to etch ferrous materials particularly pearlitic steels and mostly cast irons. Unless otherwise stated, a solution of 4% picric acid is usually implied.

Pidgeon Process

A process for production of magnesium by reduction of magnesium oxide with ferrosilicon.

Piercing

The general term for cutting (shearing or punching) openings, such as holes and slots, in sheet material, plate, or parts. This operation is similar to *blanking*; the difference is that the slug or pierce produced by piercing is scrap, while the blank produced by blanking is a useful part.

Piezoelectric

A material or crystal that becomes polarized and its surface becomes charged when a stress is applied to it. Conversely, if the material is subject to an electric field, it will expand in one direction and contract in another.

Piezoelectric Effect

The reversible interaction, exhibited by some crystalline materials, between an elastic strain and an electric field. The direction of the strain depends on the polarity of the field or vice versa. Compare with *electrostrictive effect*.

Piezoelectric Polymers

Polymers that spontaneously give an electric charge when mechanically stressed or that develop a mechanical response when an electric field is applied. Used as transducers or acoustic sensors.

Piezoelectricity

Piezoelectricity is electricity, or electric polarity, resulting from the application of mechanical pressure on a dielectric crystal. The application of mechanical stress produces in certain dielectric (electrically nonconducting) crystals an electric polarization (electric dipole moment per cubic meter) that is proportional to this stress. If the crystal is isolated, this polarization manifests itself as a voltage across the crystal, and if the crystal is short circuited, a flow of charge can be observed during loading. Conversely, application of a voltage between certain faces of the crystal produces a mechanical distortion of the material. This reciprocal relationship is referred to as the *piezoelectric effect*. The phenomenon of generation of a voltage under mechanical stress is referred to as the direct piezoelectric effect, and the mechanical strain produced in the crystal under electric stress is called the converse piezoelectric effect.

Piezoelectric materials are used extensively in transducers for converting a mechanical strain into an electrical signal. Such devices include microphones, phonograph pickups, and vibration-sensing elements. The converse effect, in which a mechanical output is derived from an electrical signal input, is also widely used in such devices as sonic and ultrasonic transducers, headphones, loudspeakers, and cutting heads for disk recording. Both the direct and converse effects are employed in devices in which the mechanical resonance frequency of the crystal is of importance. Such devices include electric wave filters and frequency-control elements in electronic oscillator circuits.

Pig

A metal casting used in remelting.

Pig Bed/Casting Machine

The bed of sand or the continuous belt of molds into which molten iron is poured to solidify as pig iron.

Pig Iron

Pig iron is the iron produced from the first melting of the ore. The melt of the blast furnace is run off into rectangular molds, forming, when cold, ingots called pigs. So-called because the iron was originally run off from the furnace into multiple branched channels formed in a bed of sand. The multiple channels were reminiscent of a family of piglets feeding from the sow. Pig iron contains small percentages of silicon, sulfur, manganese, and phosphorus, besides carbon. It is useful only for resmelting to make cast iron or wrought iron. Pig iron is either sand-cast or machine-cast. When it is sand-cast, it has sand adhering and fused into the surface, giving

more slag in the melting. Machine-cast pig iron is cast in steel forms and has a fine-grained chilled structure, with lower melting point. Pig irons are classified as Bessemer or non-Bessemer, according to whether the phosphorus content is below or above 0.10%. There are six general grades of pig iron: low-phosphorus pig iron, with less than 0.03%, used for making steel for steel castings and for crucible steelmaking; Bessemer pig iron, with less than 0.10% phosphorus, used for Bessemer steel and for acid open-hearth steel; malleable pig iron, with less than 0.20%, used for making malleable iron; foundry pig iron, with from 0.5% to 1%, and low-silicon, less than 1%, for basic open-hearth steel; and basic Bessemer, with from 2% to 3%, used for making steel by the basic Bessemer process employed in England.

Because silicon is likely to dissolve the basic furnace lining, it is kept as low as possible, 0.70%–0.90%, with sulfur not usually over 0.095%. Pig irons are also specified on the basis of other elements, especially sulfur. The sulfur may be from 0.04% to 0.10%, but high-sulfur pig iron cannot be used for the best castings. The manganese content is usually from 0.60% to 1%. Most of the iron for steelmaking is now not cast but is carried directly to the steel mill in car ladles. It is called direct metal.

Pigment (Material)

A finely divided material, pigment contributes to optical and other properties of paint, finishes, and coatings. Pigments are insoluble in the coating material, whereas dyes dissolve in and color the coating. Pigments are mechanically mixed with a coating and are deposited when the coating dries. Their physical properties generally are not changed by incorporation in and deposition from the vehicle. Pigments may be classified according to composition (inorganic or organic) or by source (natural or synthetic). However, the most useful classification is by color (white, transparent, or colored) and by function.

White Pigments

These pigments are essentially transparent to visible light. Because of the difference in refractive index between the pigment particles and the vehicles, white pigments refract the light from a multitude of surfaces and return a substantial portion in the direction of illumination without significant change in the spectral composition of the light.

The common white pigments are titanium dioxide, derived from titanium ores; white lead, from corrosion of metallic lead; zinc oxide, from burning of zinc metal; and lithopone, a mixture of zinc sulfide and barium sulfate. Pure zinc sulfide and antimony oxide are less commonly used.

Titanium dioxide may be crystallized in the rutile or anatase form, depending on the method of production. It may be further modified by surface treatment to control the rate of chalking and other properties. Rutile titanium dioxide has a higher refractive index than anatase and therefore higher hiding power, but it has a somewhat yellow color. Anatase titanium dioxide provides a purer white.

White lead pigments are the oldest of white pigments and were used extensively to provide excellent hiding power, flexibility, and durability to interior and exterior paints and enamels. Consumer protection rulings have removed white lead paints from the market, because leaded paint particles were ingested by children, with toxic effects.

Zinc oxide and lithopone pigments were extensively used in paint formulation, but have been superseded by titanium dioxide. Pure zinc oxide pigment is rarely used. Antimony oxide pigment is used chiefly in certain fire-retardant paints.

Transparent Pigments

The refractive indices of these pigments are very close to the index of the paint vehicle (about 1.54). They are used to provide bulk, control setting, and contribute to the hardness, durability, and abrasion resistance of the paint film. Because they are commonly used to add bulk to other pigments, they are called extenders. Most transparent pigments are natural minerals reduced to pigment particle size. Among the most commonly used transparent pigments are calcium carbonate (ground limestone, whiting, or chalk), magnesium silicate, bentonite clay, silicate, or barites (barium sulfate). Transparent pigments often constitute a substantial portion of a protective coating.

Colored Pigments

These pigments are available in a wide variety of colors and properties, depending upon the end use. Several hundreds have been used; the following are the most common:

Red: Iron oxides, often classified by color, include Indian red, Spanish red, Persian Gulf red, and Venetian red, a mixture of iron oxide and calcium red sulfate. Other red pigments include cadmium red (cadmium selenide) and organic reds, which are usually coal-tar derivatives either precipitated in pigment form (toners) or deposited on a transparent pigment (lakes). Organic reds include toluidines and lithols.

Orange: Chrome orange (basic lead chromate), molybdate orange (lead chromate–molybdate), and various organic toners and lakes are the most common orange pigments.

Brown: Browns are nearly always iron oxides, although certain lakes and toners are used for special purposes.

Yellow: These pigments include natural iron oxides such as ocher or sienna, or synthetic iron oxides, which are stronger and brighter, such as chrome yellow (normal lead chromate) and cadmium yellow (cadmium sulfide), and organic toners and lakes such as Hansa yellow and benzidine yellow.

Green: The most important green pigments are chrome green, a mixture of chrome yellow and Prussian blue; chromium oxide, duller but more permanent; phthalocyanine green, an organic pigment containing copper; and various other organic toners or lakes, often precipitated with phosphotungstic or phosphomolybdic acid.

Blue: The blue pigments include Prussian blue (ferric ferrocyanide, sometimes called milori or Chinese blue, depending on the shade); ultramarine, an inorganic pigment made by fusing soda sulfur and other materials under controlled conditions; phthalocyanine blue, an organic pigment containing copper; and numerous organic toners and lakes.

Purple and violet: These are nearly all organic toners or lakes. Manganese phosphate is a very weak, inorganic purple pigment.

Black: The vast majority of black pigments consist of finely divided carbon—carbon black, lampblack, and bone black—usually obtained by allowing a smoky flame to impinge on a cold surface. Black iron oxide and certain organic pigments are used with special properties required.

Special Pigments

Anticorrosive pigments are used to prevent the formation or spread of rust on iron when the metal is exposed by a break in the coating. The most common are red lead, an oxide of lead, and zinc yellow or

P

zinc chromate, a basic chromate of zinc. Other colored chromates are sometimes used. The color of red leads fades rapidly, and the anticorrosive chromates are usually very weak in tinting strength. Metallic lead is sometimes used for anticorrosive paint.

Metallic pigments are small, usually flat particles of metal, prepared for dispersion and coatings. Aluminum is most commonly used because it leafs and forms a smooth, metallic film. The flakes are sometimes colored. Bronze, copper, lead, nickel, stainless steel, and silver appear occasionally. Zinc dust, or powdered zinc, is used more often because of its excellent adhesion to galvanized iron than because of its appearance.

Luminous pigments radiate visible light when exposed to ultraviolet light. Phosphorescent pigments continue to glow for a period of time even after the exciting light has been removed; these are usually sulfides of zinc and other materials, with small amounts of additives that control the phosphorescent properties. Fluorescent pigments lose luminosity as soon as the exciting light is removed; these pigments may be sulfides, although many organic pigments have this property.

Other specialized pigments include pigments that change color at some predetermined temperature, used to indicate hot areas on motors; pigments that give a pearly appearance; and pigments that conduct electricity for printed circuits.

Coarse material such as pumice is often added when a nonslippery coating is required. Glass beads give a very high degree of refractivity in the direction of illumination and are often used in centerline paints or for signs where night visibility is required. Intumescent pigments puff up under heat, giving a fire-resistant coating.

Pilger Tube-Reducing Process

See *tube reducing*.

Pilot Arc

A low-current continuous arc between the electrode and the constricting nozzle of a plasma arc welding torch used to ionize the gas and facilitate the start of the main welding arc.

Pimple

An imperfection, such as a small protuberance of varied shape on the surface of a plastic product.

Pin (for Bend Testing)

The plunger or tool used in making semiguided, guided, or wrap-around bend tests to apply the bending force to the inside surface of the bend. In free bends or semiguided bends to an angle of 180°, a shim or block of the proper thickness may be placed between the legs of the specimen as bending is completed. This shim or block is also referred to as a pin or mandrel. See also *mandrel* (metals).

Pin Expansion Test

A test for determining the ability of a tube to be expanded or for revealing the presence of cracks or other longitudinal weaknesses, made by forcing a tapered pin into the open end of the tube.

Pin Joint

A structural joint that is free to hinge so that it does not transmit a moment.

Pin Metals

Metals for pins, originally cold-drawn common brass wire, sometimes chromium plated, now more usually hard-drawn medium-carbon steel chromium plated or for higher-quality purposes hard-drawn austenitic stainless steel.

Pinch Pass

A rolling pass producing a very small thickness reduction. Usually it is the last pass in the production of plate or sheet and is intended to provide close dimensional control. For steel, it can avoid the Lüders lines during subsequent processing.

Pinch Trimming

The trimming of the edge of a tubular metal part by pushing or pinching the flange or lip over the cutting edge of a stationary punch or over the cutting edge of a draw punch.

Pinchbeck

Brass with 5%–15% zinc, remainder copper, for cheap decorative applications, hence a derogatory term for cheap jewelry.

Pinchers

Surface disturbances on metal sheet or strip that result from rolling processes and that ordinarily appear as fernlike ripples running diagonally to the direction of rolling.

Pinch-Off

In blow molding of plastics, a raised edge around the cavity in the mold that seals off the part and separates the excess material as the mold closes around the *parison*.

Pincushion Distribution

See *positive distortion*.

Pine Tree Crystal

A type of *dendrite*.

Pinhead Blister

See *blister*.

Pinhole Eyepiece

An *eyepiece* in an *optical microscope*, or a cap to place over an eyepiece, which has a small central aperture instead of eye lens. It is used in adjusting or aligning microscopes.

Pinhole Ocular

See *pinhole eyepiece*.

Pinhole Porosity

Porosity consisting of numerous small gas holes distributed throughout a metal, found in weld metal, castings, and electrodeposited metal.

Pinholes

(1) Very small holes that are sometimes found as a type of porosity in a casting because of the microshrinkage or gas evolution during solidification. In wrought products, due to removal of inclusions or microconstituents during macroetching of transverse sections. (2) Small cavities that penetrate the surface of a cured composite or plastic part. (3) In photography, a very small circular aperture.

Pinion

The smaller of two mating gears.

Pinning

The locking into position of a dislocation by some features such as an interstitial atom.

Pin-On-Disk Machine

A tribometer in which one or more relatively moving styli (i.e., the “pin” specimen) is loaded against a flat-disk specimen surface such that the direction of loading is parallel to the axis of rotation of either the disk or the pin-holding shaft, and a circular wear path is described by the pin motion. The typical pin-on-disk arrangement resembles that of a traditional phonograph. Either the disk rotates or the pin specimen holder rotates so as to produce a circular path on the disk surface. An arrangement wherein the pin specimen is loaded against the curved circumferential surface of a flat disk is not generally considered to be a pin-on-disk machine.

Piobert Lines

See the *Lüders lines*.

Pipe

(1) The central cavity formed by contraction in metal, especially ingots, during solidification. (2) An imperfection in wrought or cast products resulting from such a cavity. (3) A tubular metal product, cast or wrought. (4) The elongated vertical cavity at the top central zone of a casting or ingot. When a molten metal solidifies and cools, it contracts. The metal tends to solidify first at the sides and bottom of the casting leaving insufficient molten metal to fill the top central area and a cavity or pipe is formed. (5) A tube or hollow section. Various terms are largely interchangeable, but “pipe” usually implies a fairly large diameter and a simple cross section. See also *extrusion pipe*.

Pipe Tap

A *tap* for making internal *pipe threads* within pipe fittings or holes.

Pipe Threads

Internal or external machine threads, usually tapered, of a design intended for making pressure-tight mechanical joints in piping systems.

Pipet

A tube, usually made of glass or plastic, used almost exclusively to deliver accurately known volumes of liquids or solutions during titration or volumetric analysis.

Pirani Gauge

An instrument used to measure the pressure inside a vacuum chamber. The gauge measures electrical resistance in a wire filament that will change in temperature depending on atmospheric pressure.

Piston-Pin Bearing

See *little-end bearing*.

Pit

A small, regular or irregular, crater in the surface of a material created by exposure to the environment, for example, corrosion, wear, or thermal cycling. See also *pitting*.

Pit Casting/Molding

Casting or molding by pouring into a refractory lined pit.

Pit Molding

Molding method in which the *drag* is made in a pit or hole in the floor.

Pitch

A high-molecular-weight material that is a residue from the destructive distillation of coal and petroleum products. Pitches are used as base material for the manufacture of certain high-modulus carbon fibers.

Pitot Tube

An instrument that measures the stagnation pressure of a flowing fluid, consisting of an open tube pointing into the fluid and connected to a pressure-indicating device. Also known as *impact tube*.

Pitting

(1) Forming small sharp cavities in a surface by corrosion, wear, or other mechanically assisted degradation. (2) *Localized corrosion* of a metal surface, confined to a point of a small area, which takes the form of cavities. (3) Loss of metal, usually by corrosion process, which penetrates to a considerable depth relative to the surface extent. Also a form of surface fatigue causing damage to gear teeth and similar sliding surfaces.

Pitting Factor

Ratio of the depth of the deepest pit resulting from corrosion divided by the average penetration calculated from weight loss.

Pivot Bearing

An axial-load, radial-load type bearing that supports the end of a rotating shaft or pivot.

P

Pivoted-Pad Bearing

See *tilting-pad bearing*.

Pixel

Shortened term for picture element. A pixel is the smallest displayable element of a digitized image; a single value of the image matrix. A pixel corresponds to the measurement of a volume element (*voxel*) in the object.

Plain Bearing

Any simple sliding-type bearing, as distinct from pad- or rolling-type bearings. See also *oil wedge*.

Plain Journal Bearing

A plain bearing in which the relatively sliding surfaces are cylindrical and in which there is relative angular motion. One surface is usually stationary and the force acts perpendicularly to the axis of rotation.

Plain Thrust Bearing

A plain bearing of the axial-load type, with or without grooves.

Plain Weave

A weaving pattern in which the warp and fill fibers alternate; that is, the repeat pattern is warp/fill/warp/fill, and so on. The two sides, or faces, of a plain weave are identical. Properties are significantly reduced relative to a weaving pattern with fewer crossovers. See *basket weave* (composites), *crowfoot weave*, and *leno weave*.

Plain-Carbon Steel

Steel containing sufficient carbon to allow it to be hardened by rapid cooling but not containing a significant amount of any other alloying element. See *steel*.

Planar

Lying essentially in a single plane.

Planar Anisotropy

A variation in physical and/or mechanical properties with respect to direction within the plane of material in sheet form. See also *plastic strain ratio*.

Planar Helix Winding

In *filament winding* of composites, a winding in which the filament path on each dome lies on a plane that intersects the dome, while a helical path over the cylindrical section is connected to the dome paths. See *helical winding*.

Planar Winding

In *filament winding* of composites, a winding in which the filament path lies on a plane that intersects the winding surface. See also *polar winding*.

Planchet

A metal disk with milled edges, ready for coining.

Planck's Constant (h)

A fundamental physical constant, the elementary quantum of action; the ratio of the energy of a photon to its frequency, which is equal to $6.62620 \pm 0.00005 \times 10^{-34} \text{ J} \cdot \text{s}$.

Plane (Crystal)

An idiomorphic face of a crystal.

Plane Glass Illuminator

A thin, transparent flat glass disk interposed in a microscope or a lens imaging system to direct light to the object without reducing the useful aperture of the lens system.

Plane Grating

In materials characterization, an optical component used to disperse light into its component wavelengths by diffraction off a series of finely spaced equidistant ridges. A plane grating has a flat substrate. See also *concave grating*, *diffraction grating*, *reflection grating*, and *transmission grating*.

Plane Strain

The stress condition in *linear elastic fracture mechanics* in which there is zero strain in a direction normal to both the axis of applied tensile stress and the direction of crack growth (i.e., parallel to the crack front), most nearly achieved in loading thick plates along a direction parallel to the plate surface. Under plane-strain conditions, the plane of fracture instability is normal to the axis of the principal tensile stress. See *fracture mechanics*.

Plane Stress

The stress condition in *linear elastic fracture mechanics* in which the stress in the thickness direction is zero, most nearly achieved in loading very thin sheet along a direction parallel to the surface of the sheet. Under plane-stress conditions, the plane of fracture instability is inclined 45° to the axis of the principal tensile stress.

Plane-Strain Fracture Toughness (K_{Ic})

The crack-extension resistance under conditions of *crack-tip plane strain*. See also *stress-intensity factor*.

Plane-Stress Fracture Toughness (K_{Ic})

In *linear elastic fracture mechanics*, the value of the crack-extension resistance at the instability condition determined from the tangency between the *R-curve* and the critical crack-extension force curve of the specimen. See also *stress-intensity factor*.

Planimetric Method

A method of measuring grain size in which the grains within a definite area are counted. See also *Jeffries' method*.

Planing

Producing flat surfaces by linear reciprocal motion of work and the table to which it is attached, relative to a stationary single-point cutting tool.

Planishing

Producing a smooth finish on metal by a rapid succession of blows delivered by highly polished dies or by a hammer designed for the purpose or by rolling in a planishing mill.

Planishing Hammer

A hammer having a working face (or two) that is square and slightly convex.

Plasma

(1) A gas of sufficient energy so that a large fraction of the species present is ionized and thus conducts electricity. Plasmas may be generated by the passage of a current between electrodes, by induction, or by a combination of these methods. (2) The condition when, at very high temperature, the atoms in a gas become highly ionized, that is, partially disassociated releasing some electrons, sometimes termed a fourth state of matter (with solid, liquid, and gas). A band in which the plasma carries the current in an electric arc. See also *plasma arc welding*.

Plasma Arc Coatings

In this process, a flow of gas, such as argon, is directed through the nozzle of a device called the plasma arc torch. When a high-current electric arc is struck within the torch between a negative tungsten electrode and the positive water-cooled copper nozzle, electrical and aerodynamical effects force the arc through the nozzle, which concentrates and stabilizes it. A substantial portion of the gas flows through the arc and is heated to temperatures as high as 16,649°C and accelerated to supersonic speeds to form an ionized gas jet called plasma. A cool layer of gas next to the nozzle wall effectively insulates the torch from the tremendous heating effect of the arc column.

Particles of refractory coating material, introduced into the plasma in either powder or wire form, are melted and accelerated to high velocity. When these molten particles strike the workpiece, they impact to form a dense, high-purity coating. Spraying of cold carbon dioxide gas, played on the workpiece, keeps it from overheating during the process and protects the purity of the coating from air oxidation.

Characteristics

The primary advantage of the process is its ability to combine the bulk properties of a base material with the surface properties of a refractory material. Furthermore, the application of the thin, tenacious coatings can be limited to the specific areas of the base material where a coding is needed, and warpage or distortion of precision parts is eliminated because of the low temperature of the base material maintained during coating.

Whether as-coated or finished, the refractory coatings have extremely good resistance to wear, abrasion, and corrosion and erosion, even under the adverse conditions of high temperature, high load, and lack of lubrication and cooling. When ground and lapped, the coatings give superior performance under conditions of fretting corrosion. Finished coating, when mated with proper materials, have generally lower coefficients of friction than most metal-to-metal combinations. This ratio is also true at elevated temperatures.

The coatings have a porosity of less than 1% and an as-coated surface finish of approximately 150 $\mu\text{in. rms}$ (root mean square), which can be finished down to better than 1 $\mu\text{in. rms}$.

Fabrication

Coatings can be applied in practically any desired thickness. But only the areas that allow the particles free access will be coated evenly. This limitation excludes narrow holes, blind cavities, and deep V-shaped grooves. All corners and edges should be rounded by a minimum 0.38 mm rad or have a minimum chamfer of 0.38 mm by 45° to prevent weak spots.

Several types of parts that can be coated are

1. Long external cylindrical parts
2. Short external cylindrical parts
3. Internal diameters
4. Rectangular flat surfaces
5. Circular flat surfaces

Since plasma arc coatings can be deposited in practically any desired thickness, it is also possible to fabricate parts by this method. The required thickness is built up on a mandrel formed to the desired internal shape of the finished part, and the mandrel is then removed chemically from the part with acid or caustic.

This method allows intricate shapes to be made of materials that are normally difficult to fabricate. But, as with flame spraying, only areas that allow the particles of coating material sufficient access will be plated evenly.

Materials

Almost any base material can be coated, even certain reinforced plastics, and any known inorganic solid that will melt without decomposition can be used as a coating material. Many basic coatings have already been established including tantalum, palladium, platinum, molybdenum, tungsten, alumina, zirconium diboride, and oxide and the three combinations of tungsten with additives to improve its properties. These additives are zirconia, chromium, and alumina.

Other coatings include the refractory metals such as columbium; some of the refractory metal compounds such as the borides of tungsten, columbium, tantalum, titanium, and chromium; the refractory carbides of columbium, hafnium, tantalum, zirconium, titanium, tungsten, and vanadium; the refractory oxides of thorium, hafnium, magnesium, cerium, and aluminum; and other pure metals such as aluminum, copper, nickel, chromium, and boron.

Properties

The properties of the coatings or parts made from all of these materials are equivalent to those of the pure materials themselves.

Plasma Arc Cutting

An arc cutting process that severs metals by melting a localized area with heat from a constricted arc and removing the molten metal with a high-velocity jet of hot, ionized gas issuing from the plasma torch. See *cutting torch* (plasma arc).

Plasma Arc Welding

(1) An arc welding process that produces coalescence of metals by heating them with a constricted arc between an electrode and the

P

workpiece (transferred arc) and the electrode and the constricting nozzle (nontransferred arc). Shielding is obtained from hot, ionized gas issuing from an orifice surrounding the electrode and may be supplemented by an auxiliary source of shielding gas, which may be an inert gas or a mixture of gases. Pressure may or may not be used, and filler metal may or may not be supplied. (2) Somewhat similar to tungsten inert gas (TIG) welding in that an arc is struck from a nonconsumed tungsten electrode carried in the torch that also supplies inert gas to protect the weld zone. However, in the plasma processes, the electrode is surrounded by a water-cooled nozzle that constricts the arc increasing the arc current density. This increases the temperature of the portion of the gas passing through the arc giving a “flame” temperature to some 15,000°C. This very high temperature compared with the normal TIG “flame” allows much deeper penetration, and hence, thicker plate can be welded in a single pass. If the constricted arc is struck between the electrode and the constricting nozzle, it is termed a nontransferred arc; if between the electrode and workpiece, it is termed a transferred arc. See also *nontransferred arc*, *transferred arc*, and *welding torch* (arc).

Plasma Carburizing

Same as *ion carburizing*.

Plasma Flame (Welding)

The zone of intense heat and light emanating from the orifice of the arc chamber resulting from energy liberated as the charged gas particles (ions) recombine with electrons. See *plasma arc welding*.

Plasma-Forming Gas

The gas, in the plasma torch, which is heated to the high-temperature plasma state by the electric arc. See also *welding torch* (arc).

Plasma Ion Deposition

See *ion implantation*.

Plasma Metallizing

See preferred term *plasma spraying*.

Plasma Nitriding

Same as *ion nitriding*.

Plasma Spraying

A *thermal spraying* process in which the coating material is melted with heat from a plasma torch that generates a nontransferred arc; molten powder coating material is propelled against the base metal by the hot, ionized gas issuing from the torch.

Plasma-Jet Excitation

In materials characterization, the use of a high-temperature plasma jet to excite an element in a sample, for example, for inductively coupled plasma atomic emission spectroscopy. Also known as dc plasma excitation.

Plasmon

A quantum of a collective longitudinal wave in the electron gas of a solid.

Plaster Mold Castings

Plaster mold casting is primarily used for producing parts in quantities that are too small to justify the use of permanent molds, yet large enough to outweigh the machining costs of sand castings. The process is noted for its ability to produce parts with high dimensional accuracy, smooth and intricate surfaces, and low porosity. On the other hand, it is limited to nonferrous metals (aluminum and copper alloys) and relatively small parts. Also, production times are relatively high because the molds take relatively long to make and are not reusable.

Process

The plaster used for molding generally consists of water mixtures of gypsum or plaster of Paris (calcium sulfate) and strengthening binders such as asbestos, magnesium silicate, and silicate flour. Impurities such as salts in section thickness are about 40–60 mils, and bosses and undercuts can be incorporated into the design.

Applications

Plaster mold castings are usually used for medium-production applications, and their cost falls between sand castings and permanent mold castings. Typical parts where the process has been used include gears, ratchet teeth, cams, handles, small housings, pistons, wing nuts, locks, valves, hand tools, and radar parts for aircraft, railroad, household, and electrical uses.

Plaster of Paris

The material (calcined gypsum), $\text{CaSO}_4 \cdot \text{O} \cdot 5\text{H}_2\text{O}$ s, is a white, gray, or pinkish-colored powder prepared by heating gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) to remove 75% of its water of crystallization.

When mixed with water and allowed to rehydrate to the dihydrate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$), there is no apparent action at first, but soon a slight stiffening takes place, and shortly after that, it “sets” to a solid mass. As set progresses, the mass begins to heat and expand, and final set is not reached until the evolution of heat has ceased and expansion is complete.

Through changes in the manufacturing process, the time of set can be varied widely (from a few minutes to many hours), and linear setting expansion also is controllable from 0.05% to 2.0%. The normal linear setting expansion of pottery plasters is –0.20% in all directions if the cast is unconfined, but under conditions of confinement, all the setting expansion may take place in one direction only.

Applications

Plasters are used in a variety of ceramic industry applications:

1. In a limited way, as chemical additives to glazes, supplying neutral, slightly soluble calcium and sulfate sulfur.
2. As a glass batching material to replace part or all of the salt cake when combined with soda ash in proper proportions. Here, the use of plaster eliminates saltwater scumming retaining the desirable fluxing property of salt cake.

3. As a bedding and leveling agent in grinding and polishing plate glass, plasters cement the glass to the grinding bed during the operation while also being easy to remove from the glass surface.
4. Optical glass mounting. Used to retain optical glass, lenses, prisms, and oculars in position while surfaces are formed to the desired curves by grinding and polishing.
5. Model making. Used in the ceramic industry generally for preparing original models.
6. Metal mold making. When suitably compounded with refractory substances, molds for the casting of nonferrous alloys such as white metal, brass, and aluminum alloys are made with plaster.
7. Low-density insulation. Used to provide green strength to mixtures of clays, nonplastic refractories, and organics.
8. Potter mold and die making. This use constitutes the principal ceramic application of plasters.

Plastic

A material that contains as an essential ingredient an organic polymer of large molecular weight, is solid in its finished state, and, at some stage in its manufacture or its processing into finished articles, can be shaped by flow. Although materials such as rubber, textiles, adhesives, and paint may in some cases meet this definition, they are not considered plastics. The terms plastic, resin, and polymer are somewhat synonymous, but the terms resins and polymers most often to note the basic material as polymerized, while the term plastic encompasses compounds containing plasticizers, stabilizers, fillers, and other additives.

Plastic Alloys and Blends

Plastics, like metals, can be alloyed. And like metal alloys, the resulting materials have different, and often better, properties than those of the base materials making up the alloys.

These alloys consist of two thermoplastics compounded into a single resin. The two polymers must be melt compatible. Some polymers are naturally compatible; others require the use of compatibilizing agents. The purpose of alloying polymers is to achieve a combination of properties not available in any single resin. There are a great many alloys available, and the list continues to grow. At present, some of the more widely used alloys are acrylonitrile, butadiene, and styrene (ABS)/polycarbonate, ABS/polyurethane, polyvinyl chloride (PVC)/acrylic, PVC/chlorinated polyethylene (CPE), polyphenylene oxide (PPO)/polystyrene, nylon/ABS, PBO/polybutylene terephthalate (PBT) thermoplastic polyester, polycarbonate/PBT thermoplastic polyester, polycarbonate/acrylate-styrene-acrylonitrile, and polysulfone/ABS.

The plastics most widely used in alloys today are PVC, ABS, and polycarbonate. The street plastics can be combined with each other or with other types of polymers.

ABS

ABS, in addition to its use with polycarbonate, can also be alloyed with polyurethane. ABS-polycarbonate alloys extend the exceptionally high impact strength of carbonate plastics to section thicknesses over 0.16 cm. ABS-polyurethane alloys combine the excellent abrasion resistance and toughness of the urethanes with the lower cost and rigidity of ABS.

The materials can be injection molded into large parts but cannot be extruded. Typical applications for which they are suitable include

such parts as wheel treads, pulleys, low load gears, gaskets, automotive grilles, and bumper assemblies.

ABS is also being successfully combined with PVC and is available commercially in several grades. One of the established grades provide self-extinguishing properties, thus eliminating the need for intumescent (nonburning) coatings in present ABS applications, such as power tool housings, where self-extinguishing materials are required. A second grade possesses an impact strength about 30% higher than general-purpose ABS. This improvement, plus its ability to be readily molded, has resulted in its use for automobile grilles.

PVC

ABS-PVC alloys are available commercially in several grades. Two of the established grades were described earlier. ABS-PVC alloys also can be produced in sheet form. The sheet materials have improved hot strength, which allows deeper draws than are possible with standard rubber-modified PVC base sheet. They also are nonfogging when exposed to the heat of sunlight. Some properties of ABS-PVC alloys are lower than those of the base resins. Rigidity, in general, is somewhat lower, and tensile strength is more or less dependent on the type and amount of ABS in the alloy.

Another sheet material, an alloy of about 80% PVC and the rest acrylic plastic, combines the nonburning properties, chemical resistance, and toughness of vinyl plastics with the rigidity and deep drawing merits of the acrylics. The PVC-acrylic alloy approaches some metals in its ability to withstand repeated blows. Because of its unusually high rigidity, sheets ranging in thickness from 1.5 to 0.5 cm can be formed into thin-walled, deeply drawn parts.

PVC is also alloyed with CPE to gain materials with improved outdoor weathering or to obtain better low-temperature flexibility. The PVC-CPE alloy applications include wire and cable jacketing, extruded and molded shapes, and film sheeting. Acrylic-base alloys with a polybutadiene additive have also been developed, chiefly for blow-molded products. The acrylic content can range from 50% to 95%, depending on the application. Besides blow-molded bottles, the alloys are suitable for thermoformed products such as tubs, trays, and blister pods. The material is rigid and tough and has good heat distortion resistance up to 82°C.

PPO

Another group of plastics, PPO, can be blended with polystyrene to produce a PPO-polystyrene alloyed with improved processing traits and lower cost than nonalloyed PPO. The addition of polystyrene reduces tensile strength and heat-deflection temperature and increases thermal expansion.

Plastic Bronze

A name once applied by makers of bearing bronzes to copper alloys that are sufficiently pliable to assume the shape of the shaft and make a good bearing by running in. These bronzes have a variety of compositions, but the plasticity is always obtained by the addition of lead, which in turn weakens the bearing. In some cases, the lead content is so high, and the tin content is so low, and the alloy is not a bronze. These copper-lead alloys have been referred to as *red metals*. The plastic bronze ingot marketed by one large foundry for journal bearings contain 65%–75% copper, 5%–7% tin, and the balance lead. *Semiplastic bronze* usually contains above 75% copper and not more than 15% lead. *ASTM alloy No. 7* has about 10% lead, 10% tin, 1% zinc, 1% antimony, and 78% copper. The compressive strength is 12,500 lb/in.² (85 MPa).

P

Plastic Constraint

See *constraint*.

Plastic Deformation

(1) The permanent (inelastic) distortion of materials under applied stresses that strain the material beyond its *elastic limit*. (2) The permanent change in dimensions remaining after all stresses have been removed. See *tensile test*.

Plastic Flow (Metals)

The phenomenon that takes place when metals are stretched or compressed permanently without rupture.

Plastic Flow (Plastics)

(1) Deformation of plastics under the action of a sustained hot or cold force. (2) Flow of semisolids in the molding of plastics.

Plastic Foam

See preferred term *cellular plastic*.

Plastic Instability

The stage of deformation in a tensile test where the plastic flow becomes nonuniform and *necking* begins. See *tensile test*.

Plastic Laminates

These are resin-impregnated paper or fabric, produced under heat in high pressure; they are also referred to as high-pressure plastic laminates. Two major categories are decorative thermosetting laminates and industrial thermosetting laminates. Most of the decorative thermosetting laminates are paper base and are known generically as papreg. Decorative laminates are usually composed of a combination of phenolic- and melamine-impregnated sheets of paper. The final properties of the laminate are related directly to the properties of the paper from which the laminate is made.

Early laminates were designed by trade names, such as Bakelite, Textolite, Micarta, Condensite, Dilecto, Phenolite, Haveg, Spauldite, Synthane, and Formica. These are designated as various types of laminates with a decorative facing layer for such uses as tabletops. Trade names now usually include a number or symbol to describe the type and grade. Textolite, for example, embraces more than 70 categories of laminates subdivided into use-specification grades, all produced in many sizes and thicknesses. Textolite 11711 is an electronic laminate for such uses as multilayer circuit boards. It is made with polyphenylene oxide resin and may have a copper or aluminum cladding.

Forms

Industrial thermosetting laminates are available in the form of sheet, rod, and rolled or molded tubing. Impregnating resins commonly used are phenolic, polyester, melamine, epoxy, and silicone. The base material or reinforcement is usually one of the following: paper, woven cotton or linen, asbestos, glass cloth, or glass mat.

Laminating resins may be marked under one trade name by the resin producer and other names by the molders of the laminate. Paraplex P resins, for example, comprise a series of polyester solutions in

monomeric styrene that can be blended with other resins to give varied qualities. But panelyte refers to the laminates that are made with phenolic, melamine, silicone, or other resin, for a variety of applications.

Plastic Memory

The tendency of a thermoplastic material that has been stretched while hot to return to its unstretched shape upon being reheated.

Plastic Powder Coatings

Although many different plastic powders can be applied as coatings, vinyl, epoxy, and nylon are most often used. Vinyl and epoxy provide good corrosion and weather resistance as well as good electrical insulation. Nylon is used chiefly for its outstanding wear and abrasion resistance. Other plastics frequently used in powder coating include chlorinated polyethers, polycarbonates, acetals, cellulose, acrylics, and fluorocarbons.

Several different methods have been developed to apply these coatings. In the most popular process, fluidized bed, parts are preheated and then immersed in a tank of finely divided plastic powders, which are held in a suspended state by a rising current of air. When the powder particles contact the heated part, they fuse and adhere to the surface, forming a continuous, uniform coating. Another process, electrostatic spraying, works on the principle that oppositely charged particles attract each other. Powder is fed through a gun, which applies an electrostatic charge opposite to that applied to the part to be coated. When the charged particles leave the gun, they are attracted to the part where they cling until fused together as a plastic coating. Other powder application methods include flock and flow coating, flame and plasma spraying, and a cloud chamber technique.

Plastic Replica

In fractography and metallography, a reproduction in plastic of the surface to be studied. It is prepared by evaporation of the solvent from a solution of plastic, polymerization of a monomer, or solidification of a plastic on the surface. See *replica*.

Plastics

Plastics are a major group of materials that are primarily noncrystalline hydrocarbon substances composed of large molecular chains whose major element is carbon. The three terms—*plastics*, *polymers*, and *resins*—are sometimes used interchangeably to identify these materials. However, the term *plastics* has now come to be the commonly used designation.

The first commercial plastic, celluloid, was developed in 1868 to replace ivory for billiard balls. Phenolic plastics, developed by Baekeland and named bakelite after him, were introduced around the turn of the century. A plastic material, as defined by the Society of the Plastics Industry, is “any one of a large group of materials consisting wholly or in part of combinations of carbon with oxygen, hydrogen, nitrogen, and other organic and inorganic elements which, while solid in the finished state, at some stage in its manufacture is made liquid, and thus capable of being formed into various shapes, most usually through the application, either singly or together, of heat and pressure.”

There are two basic types of plastics based on intermolecular bonding: thermoplastics, because of little or no cross-bonding between molecules, soften when heated and harden when cooled, no matter how often the process is repeated, and thermosets, on

the other hand, having strong, intermolecular bonding. Therefore, once the plastic is set into permanent shape under heat and pressure, reheating will not soften it.

Within these major classes, plastics are commonly classified on the basis of base monomers. There are over two dozen such monomer families or groups. Plastics are also sometimes classified roughly into three stiffness categories: rigid, flexible, and elastic. Another method of classification is by the “level” of performance or the general area of application, using such categories as engineering, general purpose, and specialty plastics, or the two broad categories of engineering and commodity plastics.

The following are some major characteristics of plastics that distinguish them from other materials, particularly metals:

1. They are essentially noncrystalline in structure.
2. They are nonconductors of electricity and are relatively low in heat conductance.
3. They are, with some important exceptions, resistant to chemical and corrosive environments.
4. They have relatively low softening temperatures.
5. They are readily formed into complex shapes.
6. They exhibit viscoelastic behavior—that is, after an applied load is removed, plastics tend to continue to exhibit strain or deformation with time.

Polymers can be built of one, two, or even three different monomers and are termed homopolymers, copolymers, and terpolymers, respectively. The geometrical form can be linear or branched. Linear or unbranched polymers are composed of monomers linked end-to-end to form a molecular chain that is like a simple string of beads or a piece of spaghetti. Branched polymers have side chains of molecules attached to the main linear polymer. These branches can be composed either of the basic linear monomer or of a different one. If the side molecules are arranged randomly, the polymer is atactic; if they branch out on one side of the linear chain in the same plane, the polymer is isotactic, and if they alternate from one side to the other, the polymer is syndiotactic.

Plastics are produced in a variety of different forms. Most common are plastic moldings, which range in size from 2 cm to several meters. Thermoplastics, such as polyvinyl chloride (PVC) and polyethylene, are widely used in the form of plastic film and plastic sheeting. The term *film* is used for thicknesses up to and including 0.25 cm, while sheeting refers to thicknesses over that.

Both thermosetting and thermoplastic materials are used as plastic coatings on metal, wood, paper, fabric, leather, glass, concrete, ceramics, or other plastics. There are many coating processes, including knife or spread coating, spraying, roller coating, dipping, brushing, calendaring, and the fluidized-bed process. Thermosetting plastics are used in high-pressure laminates to hold together the reinforcing materials that comprise the body of the finished product. The reinforcing materials may be cloth, paper, wood, or glass fibers. The end product may be plain flat sheets or decorative sheets as in countertops, rods, tubes, or formed shapes.

Plastic Additives

Almost all plastics contain one or more additive materials to improve their physical properties and processing characteristics or to reduce costs. There is a wide range of additives for use with plastics, including antimicrobials, antistatic agents, clarifiers, colorants, fillers, flame retardants, foaming agents, heat stabilizers, impact modifiers, light stabilizers, lubricants, mold release agents, odorants, plasticizers, reinforcements, and smoke retardants.

Fillers

Fillers are probably the most common of the additives. They are usually used to either provide bulk or modify certain properties. Generally, they are inert and thus do not react chemically with the resin during processing. The fillers are often cheap and serve to reduce costs by increasing bulk. For example, wood flour, a common low-cost filler, sometimes makes up 50% of a plastic compound. Other typical fillers are chopped fabrics, asbestos, talc, gypsum, and milled glass. Besides lowering costs, fillers can improve properties. For example, asbestos increases heat resistance, and cotton fibers improve toughness.

Plasticizers

Plasticizers are added to plastic compounds either to improve flow during processing by reducing the glass transition temperature or to improve properties such as flexibility. Plasticizers are usually liquids that have high boiling points, such as certain phthalates. Substances that are themselves polymers of low molecular weight, such as polyesters, are also used as plasticizers.

Stabilizers

Stabilizers are added to plastics to help prevent breakdown or deterioration during molding or when the polymers are exposed to sunlight, heat, oxygen, ozone, or combinations of these. Thus there is a wide range of compounds, each designated for a specific function. Stabilizers can be metal compounds, based on tin, lead, cadmium, barium, and others. And phenols and amines are added antioxidants that protect the plastic by diverting the oxidation reactions to themselves.

Catalysts

Catalysts, by controlling the rate and extent of the polymerization process in the resin, allow the curing cycle to be tailored to the processing requirements of the application. Catalysts also affect the shelf life of the plastics. Both metallic and organic chemical compounds are used as catalysts.

Colorants

Colorants, added to plastics for decorative purposes, come in a wide variety of pigments and dyestuffs. The traditional colorants are metal-based pigments such as cadmium, lead, and selenium. More recently, liquid colorants, composed of dispersions of pigments in a liquid, have been developed.

Flame Retardants

Flame retardants are added to plastic products that must meet fire-retardant requirements, because polymer resins are generally flammable, except for such notable exceptions as PVC. In general, the function of the fire retardants is limited to the spread of fire. They do not normally increase heat resistance or prevent the plastic from charring or melting. Some fire-retardant additives include compounds containing chlorine or bromine, phosphate-ester compounds, antimony trioxide, alumina trihydrate, and zinc borate.

Reinforced Materials

Reinforcement materials in plastics are not normally considered additives. Usually in fiber or mat form, they are used primarily to

P

improve mechanical properties, particularly strength. Although asbestos and some other materials are used, glass fibers are the predominant reinforcement for plastics.

Plastics Processing

Plastics processing includes those methods and techniques used to convert plastic materials in the form of pellets, granules, powders, sheets, fluids, or preforms into formed shapes or parts. The plastic materials may contain a variety of additives that influence the properties as well as the process ability of the plastics. After forming, the part may be subjected to a variety of ancillary operations such as welding, adhesive bonding, and surface decorating (painting, metallizing).

As with other materials of construction, processing of plastics is but one step in the normal design-to-finished-part sequence. The choice of process is influenced by economic considerations, number and size of finished parts, and complexity of postfinishing operations, as well as the adaptability of the plastics to the process.

Injection Molding

This process consists of heating and homogenizing plastic granules in a cylinder until they are in the fluid form sufficient to allow pressure injection into a relatively cold mold where they solidify and take the shape of the mold cavity. For thermoplastics, no chemical changes occur within the plastic, and consequently, the process is repeatable. Injection molding of thermosetting resins differs primarily in that the cylinder heating is designed to homogenize and preheat the reactive materials and the mold is heated to complete the chemical cross-linking reaction to form an intractable solid. Solid particles, in the form of pellets or granules, constitute the main feed for injection moldable plastics. The major advantages of the injection molding process are the speed of production, minimal requirements for postmolding operations, and simultaneous multipart molding.

The development of reaction injection molding (RIM) allowed the rapid molding of liquid materials. In these processes, cold or warm, two highly reactive, low-molecular-weight, low-viscosity resin systems are first injected into a mixing head and from there into a heated mold, where the reaction to a solid is completed.

Polymerization and cross-linking occur in the mold. This process has proved particularly effective for high-speed molding of such materials as polyurethanes, epoxies, polyesters, and nylons.

Extrusion

In this process, plastic pellets or granules are fluidized, homogenized, and continuously formed. Products made this way include tubing, pipe, sheet, wire and substrate coatings, and profile shapes. The process is used to form very long shapes or a large number of small shapes that can be cut from the long shapes. The homogenizing capability of extruders is used for plastic blending and compounding. Pellets used for other processing methods, such as injection molding, are made by chopping long filaments of extruded plastic.

Blow Molding

This process consists of forming a tube (called a parison) and introducing air or other gas to cause the tube to expand into a free-blown hollow object or against a mold for forming into a hollow object with a definite size and shape. The parison is traditionally made by extrusion, although injection-molded tubes have gained prominence because they do not require postfinishing, have better dimensional

tolerances and wall thicknesses, and can be made unsymmetrical and in a higher volume production.

Thermoforming

Thermoforming is the forming of plastic sheets into parts through the application of heat and pressure. Pressure can be obtained through the use of pneumatics (air) or compression (tooling) or vacuum. Tooling for this process is the most inexpensive compared to other plastic processes, accounting for the popularity of the method. It can also accommodate very large parts as well as small parts, which are useful in low-cost prototype fabrication.

Rotational Molding

In this process, finely ground powders are heated in a rotating mold until melting or fusion occurs. If liquid materials, such as vinyl plastisols, are used, the process is often called slush molding. The melted or fused resin uniformly coats the inner surface of the mold. When cooled, a hollow finished part is removed. The processes require relatively inexpensive tooling, are scrap-free, and are adaptable to large, double-walled, hollow parts that are strain-free and of uniform thickness. The processes can be performed by relatively unskilled labor. On the other hand, the finely ground plastic powders are more expensive than pellets, or sheet, thin-walled parts cannot be easily made, and the process is not suited for large production runs of small parts.

Compression and Transfer Molding

Compression molding is one of the oldest molding techniques and consists of charging a plastic powder or preformed plug into a mold cavity, closing a mating mold half, and applying pressure to compress, heat, and cause flow of the plastic to conform to the cavity shape. The process is primarily used for thermosets, and consequently, the mold is heated to accelerate the chemical cross-linking.

Transfer molding is an adaptation of compression molding in that the molding powder or preform is charged to a separate preheating chamber and, when appropriately fluidized, injected into a closed mold. The process predates, yet closely parallels, the early techniques of ram injection molding of thermoplastics. It is mostly used for thermosets and is somewhat faster than compression molding. In addition, parts are more uniform and more dimensionally accurate than those made by compression molding.

Foam Processes

Foamed plastic materials have achieved a high degree of importance in the plastic industry. Foams can be made in a range from soft and flexible to hard and rigid. There are three types of cellular plastics: blown (expanded matrix, such as a natural sponge), syntactic (the encapsulation of hollow organic or inorganic microspheres in the matrix), and structural (dense outer skin surrounding a foamed core).

There are seven basic processes used to generate plastic foams. They include the incorporation of a chemical blowing agent that generates gas (through thermal decomposition) in the polymer liquid or melt; gas injection into the melt, which expands during pressure relief; generation of gas as a by-product of a chemical condensation reaction during cross-linking; volatilization of a low-boiling liquid (e.g., Freon) through the exothermic heat of reaction; mechanical dispersion of air by mechanical means (whipped cream); incorporation of nonchemical gas-liberating agents (adsorbed gas or finely divided carbon) into the resin mix,

which is released by heating; and expansion of small beads of thermoplastic resin containing a blowing agent through the external application of heat.

Structural foam differs from other foams in that the part is produced with a hard integral skin on the outer surfaces in a cellular core in the interior. They are made by injection-molding liquefied resins containing chemical blowing agents. The initial high injection pressure causes the skin to solidify against the mold surface without undergoing expansion. The subsequent reduction in pressure allows the remaining material to expand and fill the mold. Coinjection (sandwich) molding permits injection molding of parts containing a thermoplastic core within an integral skin of another thermoplastic material. When the core is foam, an advanced form of structural foam is produced.

Reinforced Plastics/Composites

These are plastics whose mechanical properties are significantly improved because of the inclusion of fibrous reinforcements. The wide variety of resins and reinforcements that constitute this group of materials led to the more generalized description "composites."

Composites consist of two main components, the fibrous material in various physical forms and the fluidized resin, which will convert to a solid. There are fiber-reinforced thermoplastic materials, and

these are typically processed in standard thermoplastic processing equipment.

The first step in any composite fabrication procedure is the impregnation of the reinforcement with the resin. The simplest method is to pass the reinforcement through a resin bath and use the wet impregnate directly. For easier handling and storage, the impregnated reinforcement can be subjected to heat to remove impregnating solvents or advance the resin cure to a slightly tacky or dry state. The composite in this form is called a prepreg. This B-stage condition allows the composite to be handled, yet the cross-linking reaction has not proceeded so far as to preclude final flow and conversion into a simultaneous part, when further heat or pressure is applied.

Premixes, often called bulk molding compounds, are mixtures of resin, inert fillers, reinforcements, and other formulation additives that form a puttylike rope, sheet, or preformed shape.

Converting these various forms of composite precursors to final-part shape is achieved in a number of ways. Hand lay-up techniques entail an open mold onto which the impregnated reinforcement or prepreg is applied layer by layer until the desired thicknesses and contours are achieved; see Figure P.1a depicting techniques for producing reinforced plastics and composites. The thermoset resin is then allowed to harden (cure). Often the entire configuration will be enclosed in a transparent sealed bag (vacuum bag) so that

FIGURE P.1 Techniques for producing reinforced plastics and composites. (a) Hand lay-up technique for reinforced thermosets, (b) vacuum bag molding method, (c) spray-up method, (d) matched metal die molding, (e) filament winding. (From *McGraw-Hill Encyclopedia of Science and Technology*, 8th edn., Vol. 14, McGraw-Hill, New York, p. 45. With permission.)

P

a vacuum can be applied to remove unwarranted volatile ingredients and entrained air for improved densification of the composite (Figure P.1b). External heat may be applied to accelerate the process. Often a bagged laminate will be inserted into an autoclave so that the synergistic effects of heat, vacuum, and pressure can be obtained. At times, a specially designed spray apparatus is used that simultaneously mixes and applies a coating of resin and shop reinforcement to a mold surface (Figure P.1c). This technique is particularly useful for large structures such as boat hulls and truck cabs, covering complex shapes as readily as simple configurations.

Matched die compression molding resembles normal compression molding, although the pressures are considerably lower (Figure P.1d). Premix molding is essentially the same process, except that premix compounds are used. *Pultrusion* is a term coined to describe the process for the continuous extrusion of reinforced plastic profiles. Strands of reinforcement are drawn (pulled) through an impregnating tank, the forming die, and finally a curing area (radio-frequency exposure). Filament winding is a process in which the continuous strands of reinforcement are drawn through an impregnating bath and then wound around a mandrel to form the part (Figure P.1e). This technique is mostly used for the formation of hollow objects such as chemical storage tanks or chemically resistant pipe. Advanced automated processes, such as ply cutting, tape laying and contouring, and ply laminating, are providing improved parts and reduced costs particularly in the aerospace industry.

Casting and Encapsulation

Casting is a low-pressure process requiring nothing more than a container in the shape of the desired part. For thermoplastics, liquid monomer is poured into the mold and, with heat, allowed to polymerize in place to a solid mass. For vinyl plastisols, the liquid is fused with heat. Thermosets, usually composed of liquid resins with appropriate curatives and property-modifying additives, are poured into a heated mold in which the cross-linking reaction completes the conversion to a solid. Often a vacuum is applied to gasify the resultant part for improved homogeneity.

Encapsulation and potting are terms for casting processes in which a unit or assembly is encased or unimpregnated, respectively, with a liquid plastic, which is subsequently hardened by fusion or chemical reaction. There are several low-pressure plastic processes: casting, potting, encapsulating, and sealing. These processes are predominant in the electrical and electronic industries for the insulation and protection of components.

Calendering

In the calendering process, a plastic is masticated between two rolls that squeeze it out into a film that then passes around one or more additional rolls before being stripped off as a continuous film. Fabric or paper may be fed through the latter rolls, so that they become impregnated with the plastic.

Plastic Strain

Dimensional change that does not disappear when the initiating stress is removed. Usually accompanied by some *elastic deformation*.

Plasticity

The property of a material that allows it to be repeatedly deformed without rupture when acted upon by a force sufficient to cause deformation and which allows it to retain its shape after the applied force has been removed.

Plasticizer

(1) A material incorporated in a plastic to increase its workability, flexibility, or distensibility. Normally used in thermoplastics. (2) A material added to a plastic (or polymer) of lower molecular weight to reduce stiffness and brittleness, resulting in a lower glass transition temperature for the polymer. (3) A material added to an adhesive to cause a reduction in melt viscosity, lower the temperature of the second-order transition, or lower the elastic modulus of the solidified adhesive. See also *modifier*.

Plastic-Strain Ratio (*r*-Value)

In formability testing of metals, the ratio of the true width strain to the true thickness strain in a sheet tensile test,

$$r = \epsilon_w / \epsilon_t$$

r = plastic strain ratio

ϵ_w = plastic strain in-plane or in width

A formability parameter that relates to drawing and is also known as the anisotropy factor. A high r -value indicates a material with good drawing properties.

Plastic-Zone Adjustment (r_p)

In *linear elastic fracture mechanics*, in addition to the *physical crack size* to account for plastic crack-tip deformation enclosed by a linear-elastic stress field. See also *crack-extension resistance* (K_{Rc}).

Plastigel

A plastisol exhibiting gel-like flow properties. One having an effective yield value.

Plastisol Coatings

Vinyl plastisols, or pastes, as they are described in Europe, are suspensions of vinyl resin in nonvolatile oily liquids known as plasticizers. They vary in viscosity from a motor oil consistency to a puttylike dough. In the more viscous state, the plastisol is termed *plastigel*, while the more fluid materials to which volatile diluents have been added are known as *modified plastisols*. Modified plastisols differ from organosols in the function of the volatile components. In organosols, the volatiles are used as resin dispersants, whereas in modified plastisols, they serve as diluents to adjust fluidity and are generally present in small quantities.

The polyvinyl chloride resin, resembling confectioner's sugar, is blended into a mixture of one or more plasticizers to form a suspension. This fluid remains essentially unchanged until heat is applied. During the heating process, the dispersion first sets or gels; this is followed by solution or fusion of the resin in the hot plasticizer to form a single-phase solid solution. Upon cooling, the coating assumes the properties of a tough, rubbery plastic.

These plastisols have no adhesion to metals or dense, nonporous substrates and consequently require the use of adhesive primers for bonding. To a large extent, the nature of these primers determines the suitability of plastisol coatings for specific applications.

Application Methods

The fluidity or absence of fluidity in the liquid plastisol is sometimes deceiving. These materials are supplied at very high solid content

and consequently exhibit non-Newtonian flow (viscosity varies with applied shear). While the viscosity cup is satisfactory for many paints and lacquers and may even suffice for organosols, it can only serve to mislead the plastisol user. Viscosity of plastisols should be specified and measured using a viscometer capable of operating over a range of shear rates preferably within the area of use.

Spread Coating

Roller and knife coaters are the two major types of spread coating equipment used for handling plastisols. Fabric, paper, and even strip steel are all being coated with this type of process. Compound viscosity characteristics, speed of coating, clearance between the web and the knife or roll, and the type and angle of the knife are all factors in determining the quality of the coating. Heavy paper and fabric coatings, which will withstand folding and forming, may be applied to porous stock without danger of penetration or strike-through. The momentary application of heat to the coated side of the stock will fuse the plastisol with a minimum of thermal action on the paper.

Plastisol-coated strip steel is currently being produced by roller-coating processes for use by appliance and other manufacturers.

Dip Coating

Two dip-coating processes are available. In hot dipping, the object for coating is prebaked, prior to immersion in the plastisol. The heat content in the article serves to gel a deposit on the surface of the object. This gelled coating must then be fused by baking. Plastisol formulation and temperature, dipping rate, mass, shape, and heat content of the article to be coated all serve to determine the thickness and nature of deposit.

Cold-dip processes permit the application of from 1 to 60 mils per coat without the necessity of a prebake operation. Cold dips lend themselves to conveyor line coating of products. These coatings have a high yield value and permit controlled film thicknesses without the presence of sags or drips to mar the appearance.

Spray Coating

Plastisols may be spray applied through either pressure or suction guns, but generally the pressure equipment is preferred because it permits faster delivery with a minimal use of volatile diluents. Airless spray equipment is currently available that operates at fluid pressures in excess of 13.6 MPa and requires no atomizing air. This airless spray process is reported to give extreme smoothness to highly thixotropic formulations.

Properties

Although plastisols may be modified with slight additions of volatile diluents, their fluidity is mainly due to the presence of large quantities of plasticizer. Unlike the fluid phase of the organosol, which is largely volatile, the plasticizers remain behind after baking, as a portion of the fused film. Thus, the plastisol tends to be softer and more resilient than the organosol. Its low volatile content (or its absence altogether) permits wide baking latitude by eliminating the problem of mud cracking and reducing the solvent entrapment tendency found in organosols. Film thicknesses may range from 2 to 250 mils per coat.

Uses

Plastisols, because of their ability to be applied readily in heavy thicknesses, found early success in the electroplating field as rack

coatings. The plastisol serves as an insulation, confining current to the work being plated, and is resistant to chemical attack by plating solutions. The use of plastisols as linings for tanks, chemical equipment, and steel drums.

In fabric coating, they have replaced solution coatings by eliminating the need for expensive solvents lost in the baking operation. Rubber has been replaced by vinyl plastisols and organosols as coatings for wire baskets because of their superior resistance to moisture and detergents.

One of the most dramatic applications of plastisols is as a lining for kitchen dishwashers. The use of a plastisol lining permitted a lightweight tub design not possible with porcelain enameling in which firing resulted in buckling and warping of light-gauge steel. Plastisols also served to reduce scrap units since defects may be readily patched and repaired. The resistance to impact damage, etching, and enamel erosion are other factors that prompted manufacturers to select plastisols for this application.

A list of applications on the properties related to the specific application follow:

Application	Related Property
<i>Industrial:</i> Tool handles, stair treads, conveyor hooks, conveyor rollers, railings	Resiliency, thermal and electrical insulating qualities, resistance to abrasion
<i>Electrical:</i> Bus bar conduit boxes, battery clamps and cases, toggle switches, electroplating racks, and plating barrels	Dielectric strength, electrical resistivity, resistance to moisture and chemicals
<i>Linings:</i> Tanks, ductwork, pumps, filter presses, centrifugal cleaners, dishwasher tubs, piping, drums, and shipping containers	Resistance to abrasion and impact, resistance to moisture and chemicals
<i>Wire goods:</i> Dish-drain baskets, egg baskets, deep-freeze baskets, refrigerator shelves, record racks, clothes hangers	Resistance to moisture, detergents, staining, and resiliency
<i>Miscellaneous:</i> Bottles and glassware, glove coating, bobby pin coatings	Resiliency and aesthetic qualities, abrasion resistance, softness

Plastisols

Mixtures of vinyl resins and plasticizers that can be molded, cast, or converted to continuous films by the application of heat. If the mixtures contain volatile thinners as well, they are known as *organosols*.

Plastisols are dispersions of high-molecular-weight vinyl chloride polymer or copolymer resins in nonaqueous liquid plasticizers, which do not dissolve the resin at room temperature. Plastisols are converted from liquids to solids by fusing under heat, which causes the resin to dissolve in the plasticizers.

There are many advantages in molding with plastisols each varying in importance according to the particular type of molding application. Vinyl plastisol is supplied as a liquid and consequently is easy to handle. The material requires no catalysts or curing agents to convert it to a solid, only moderate heat in the range of 149°C–204°C. Vinyl plastisol does not require a long baking cycle nor high pressures to fuse and shape it. Consequently, lightweight inexpensive molds are suitable for molding. It can be formulated to have a virtually indefinite shelf life. Plastisols are usually 100% solids and shrinkage from the mold is at an absolute minimum, thus assuring that the molded object is exact and consistent.

P

Properties

Chemical and physical properties of plastisols can be varied throughout a wide range. This versatility makes plastisols adaptable to a multitude of end uses.

The following general ranges indicate the properties that may be compounded into plastisols:

- Specific gravity: 1.05–1.35
- Tensile strength: As required to 27.2 MPa
- Elongation: As required to 600%
- Flexibility: Good to a temperature as low as -55°C
- Hardness: From 10 to 100 on the Shore A durometer scale; up to 80 on the Shore D durometer scale
- Chemical resistance: Outstanding to most acids, alkalies, detergents, oils, and solvents
- Heat resistance: Can resist 107°C for as long as 2000 h and 232°C for over 2 h
- Electrical properties: Dielectric strength at a minimum of 400 V/mil in thicknesses of 3 mils and over
- Flammability: Slow burning to self-extinguishing
- Colors: All colors available including phosphorescent and fluorescent shades

Molding Methods

There are several different methods by which plastisols may be molded.

Pour and Injection

Two of the simplest methods are pour molding and low-pressure injection molding. The first method entails merely pouring plastisol into a cavity until it is filled and subsequently fusing the compound. The system is used in manufacturing products such as plastic doilies, sink stoppers, and display plaques.

If the mold is closed, a low-pressure injection system such as a grease gun can be used to inject the liquid plastisol into the cavity. A low-pressure injection mold should be designed with bleeders at the extremities of the cavity to ensure complete filling of the mold as well as to relieve the minor pressure on the mold surface caused by expansion during the heating. Laboratory models, novelties, and electrical harnesses are products that are commonly low-pressure injection molded with vinyl plastisol.

Heating sources used for molding plastisols vary according to the particular product under consideration. For shallow, open molds, such as those for plastic doilies, radiant heat would be unsatisfactory. When this type of heat is used, the material thickness should not be so great that the open surface exposed to the heat overfuses in the time taken for the temperature to reach the mold surface of the part. Conductive heat is another source for fusing plastisol, in particular when closed molds are employed. Immersing the mold in a hot bath or using cartridge heaters are two conductive heating methods. A more commonly used method of fusion is convection heat. The advantage of a convection oven, in particular a forced air type, is that the entire inner area of the oven, and consequently the entire surface of the mold, is maintained at a constant temperature, ensuring a more even heat transfer through the mold.

Pour and low-pressure injection molds usually are made of aluminum, electroformed copper, brass, or steel. The thickness of the metal should be kept to a minimum for good heat transfer yet should be thick enough to withstand expansion pressure during fusing.

In-Place Molding

Another molding process, which is somewhat similar to the foregoing methods, is in-place molding. This method permanently

attaches plastisol to another component during the fusing process. The combination serves an important functional purpose and usually eliminates the need for several assembly steps. In-place molding is most commonly used in forming seals and gaskets of various sorts.

Gaskets are applied to vitrified clay pipe by pouring plastisol into special molds on the bell and spigot ends. Such gaskets compensate for inherent out of roundness of the pipe. Flowed-in gaskets also are applied to bottle caps and jar lids.

Dip Molding

When a hollow object is to be molded and the internal dimensions are of importance, many times a dip molding process is employed. The metal molds are shaped according to the interior design of the molded object. They are usually solid and are made of cast or machined aluminum, machined brass, steel, or ceramic. These molds are preheated to a temperature in the range of 149°C – 204°C , dipped into the plastisol, and allowed to dwell until the proper thickness has gelled on the mold. To eliminate drips or sags, the mold is withdrawn at a rate that does not exceed the rate at which the liquid residue drains from the gelled coating. The thickness of this coating can be varied by altering the preheating time and temperature as well as the dwell time. A dip molding system can be easily conveyORIZED. In such a system, the mandrels holding the molds would be conveyed through a preheat oven, dipping station, fusing oven, cooling station, and stripping station.

Slush Molding

Another method for molding hollow pieces is slush molding. In this process, an open-end metal mold is heated to a temperature in the range of 149°C – 204°C and then filled with plastisol. The plastisol is allowed to dwell until the desired thickness has gelled on the inner surface of the mold and then the remaining liquid in the mold is poured back into a reservoir for use again. The mold with the gelled inner coating is placed in an oven where the plastisol is fused. Upon cooling, the plastisol part is stripped from the mold, retaining the design of its inner surface on the exterior of the piece. Molds of electroformed copper or fine sand-cast aluminum are usually used for slush molding.

This process is generally known as the single-pour system of slush molding. For a mold of intricate detail, a two-pour method often is used. In this process, the mold is filled when it is cold, vibrated to remove bubbles, and then emptied, leaving a thin film of plastisol on the inner surface. In this way, the plastisol does not have a chance to gel before flowing into the mold extremities.

Rotational Molding

Completely enclosed hollow parts can be produced by rotational molding. A measured amount of plastisol is poured into one-half of a two-piece mold. The mold is closed and rotated in two or more planes while being heated. During this rotation, the plastisol flows, gels, and fuses evenly over the interior walls of the mold. Molds for this operation are either electroformed copper or cast or machined aluminum, and the molds are arranged in clusters or “gangs” so that the maximum number of molds can be operated per spindle.

In rotational molding, it is possible to vary the thickness of the walls of the molded piece. One way this can be accomplished is by rotating the mold more in one plane than in another.

A few familiar products manufactured by this process are toys and novelties such as dolls and beach balls, swimming pool floats, and artificial fruit.

Combinations

In many cases, several of the aforementioned molding methods are combined to produce a product made from plastisol. For example, vinyl foam products such as armrests, toys, or electrical harnesses are manufactured by first forming a tough vinyl skin by spraying, slush molding, or rotational molding. The interior then is formed by casting, low-pressure injecting, or rotational molding a vinyl plastisol foam within the pregelled skin.

Plastohydrodynamic Lubrication

A condition of lubrication in which the friction and film thickness between two bodies in relative motion are determined by plastic deformation of the bodies in combination with the viscous properties of the lubricant at the prevailing pressure, temperature, and rate of shear. Compare with *elastohydrodynamic lubrication*.

Plastometer

An instrument for determining the flow properties of a thermoplastic resin by forcing the molten resin through a die or orifice of specific size at a specified temperature and pressure.

Plate

A flat-rolled metal product of some minimum thickness and width arbitrarily dependent on the type of metal. Plate thicknesses commonly range from 6 to 300 mm (0.25–12 in.) and widths from 200 to 2000 mm (8–80 in.). See also *plating*.

Plate Glass

Flat glass formed by a rolling process, ground and polished on both sides, with surfaces essentially plain and parallel.

Plate Martensite

Martensite formed partly in steel containing more than approximately 0.5% C and solely in steel containing more than approximately 1.0% C that appears as lenticular-shaped plates (crystals).

Platelet Alpha Structure

In titanium alloys, *acicular alpha* of a coarser variety, usually with low aspect ratios. This microstructure arises from cooling α or α - β alloys from temperatures at which a significant fraction of β phase exists.

Platelets

Flat particles of metal powder having considerable thickness. The thickness, however, is smaller when compared with the length and widths of the particles. See also *particle shape*.

Platen

(1) The sliding member, *slide*, or *ram* of a metal-forming press. (2) The mounting plates of a plastic-forming press, to which the entire mold assembly is bolted. (3) A part of a resistance welding, mechanical testing, or other machine with a flat surface to which dies, fixtures, backups, or electrode holders are attached, which

transmits pressure or force. (4) A flat working surface of a press or other equipment. It may contact the workpiece or carry tooling and movable jigs, etc. (5) A series of tubes or bars joined by welding to form a plate.

Platen Force

The force available at the movable platen in a resistance welding machine that causes upsetting in flash or upset welding.

Plating

(1) Forming an adherent layer of metal on an object, often used as a shop term for *electroplating*. (2) Metal in plate form. (3) The application of a film or coating of some material to another material, for example, chromium is applied to brass for mainly decorative purposes and zinc is applied to steel to provide corrosion resistance. See also *electroplating*, *galvanizing*, *electrodeposition* and *electroless plating*.

Plating Rack

A fixture used to hold work and conduct current to it during *electroplating*.

Plating Range

The current-density range over which a satisfactory electroplate can be deposited.

Platinum

Platinum, a whitish-gray metal, symbol Pt, is more ductile than silver, gold, or copper and is heavier than gold. The melting point is 1769°C, and the specific gravity is 21.45. The hardness of the annealed metal is 45 Brinell, and its tensile strength is 117 MPa; when hard rolled, the Brinell hardness is 97 and tensile strength 34 MPa. Electrical conductivity is about 16% that of copper. The metal has a face-centered cubic lattice structure and it is very ductile and malleable. It is resistant to acids and alkalis, but dissolves in aqua regia. Platinum is widely used in jewelry, but because of its heat resistance and chemical resistance, it is also valued for electric contacts and resistance wire, thermocouples, standard weights, and laboratory dishes. Generally too soft for use alone, it is almost always alloyed with harder metals of the same group, such as osmium, rhodium, and iridium. An important use of the metal, in the form of gauze, is as a catalyst. Platinum gauze is of high purity in standard meshes of 18–34/cm, with wire from 0.020 to 0.008 cm in diameter. Dental foil is 99.99% pure and of maximum softness. Platinum foil for other uses is made in thicknesses as thin as 0.0005 cm. Platinum powder comes in fine submesh particle size. It is made by chemical reduction and is at least 99.9% pure, with amorphous particles 0.3–3.5 μ m in diameter. Platinum flake has the powder particle in the form of tiny laminar platelets that overlap in the coating film.

Because of the high resistance of the metal to atmospheric corrosion even in sulfur environments, platinum coatings and electroplating are used on springs and other functioning parts of instruments and electronic devices where precise operation is essential. Coatings are also produced by vapor deposition on platinum compounds; thin coatings, 0.0005 cm or less, are made by painting the surface with a solution of platinum powder in an organic vehicle and then firing to drive off the organic material, leaving an adherent coating of platinum metal.

P

Platinum is sometimes used in glazes to obtain luster and metallic effects. Liquid bright platinum and liquid bright palladium (an element of the platinum group) are preparations used in metallic decorations. As platinum produces a better silver affect than silver itself and is less likely to tarnish, platinum is preferred to that metal. A luster produced from a strong solution of platinum chloride and spirits or oil of lavender upon firing gives a steely appearance that is nearly opaque. Another method consists of precipitating the metal from its solution in water by heating it with a solution of caustic soda and glucose. The metal is mixed with 5% bismuth subnitrate, applied to the ware by painting, and fired in a reducing atmosphere.

Platinum Alloys

Platinum is alloyed to obtain greater hardness, strength, and electrical resistivity. Because most applications require freedom from corrosion, the other platinum metals are usually employed as alloying agents.

Platinum–Iridium

Iridium is added to platinum most often used to provide improved mechanical properties. It increases resistance to corrosion while the alloy retains its workability. Up to 20% iridium, the alloys are quite ductile. With higher iridium content, fabrication becomes difficult.

Platinum–iridium alloys are employed for instruments, magneto contacts, and jewelry. The alloys are hard, tough, and noncorrosive. An alloy of 95% platinum and 5% iridium, when hardworked, has a Brinell hardness of 170; an alloy with 30% iridium has a hardness of 400. Alloys containing 5% of platinum and 10% of iridium are used for jewelry manufacture, while alloys containing 25% of platinum and 30% of iridium are employed for making surgical instruments. An alloy of 80% platinum and 20% iridium is used for magneto contact points, and an alloy of 90% platinum and 10% iridium is widely used for electric contacts in industrial control devices. The addition of iridium does not alter the color of the platinum. Alloy with 5% platinum dissolves readily in aqua regia, while an alloy with 30% iridium dissolves slowly.

Platinum–Rhodium

The addition of rhodium to platinum also provides improved mechanical properties to platinum and increases its resistance to corrosion. For applications at high temperatures, platinum–rhodium alloys are preferred because of retention of good mechanical properties including good hot strength and very little tendency toward volatilization or oxidation.

Platinum–rhodium alloys are used for thermocouples for temperatures above 1100°C. The standard thermocouple is platinum versus platinum with 10% rhodium. Other thermocouples for higher operating temperatures use platinum–rhodium alloys in both elements. The alloys of platinum–rhodium are widely used in the glass industry, particularly as glass-fiber extrusion bushings. Rhodium increases the high-temperature strength of platinum without reducing its resistance to oxidation. Platinum–rhodium gauze for use as a catalyst in producing nitric acid from ammonium contains 90% platinum and 10% rhodium.

Platinum–Ruthenium

Alloying platinum with ruthenium has the most marked effect upon both hardness and resistivity. However, the limit of workability is reached at 15% ruthenium. The lower cost and the lower specific gravity of ruthenium offer an appreciable economic benefit as an alternate to other platinum alloys.

Platinum–ruthenium alloy, with 10% ruthenium, has a melting point of 1800°C and electrical conductivity 4% that of copper.

Platinum–Gold

Platinum–gold alloys cover a wide range of compositions and provide distinct chemical and physical characteristics.

Platinum–Cobalt and Platinum–Nickel

Platinum–cobalt alloys, with about 23% cobalt, are used for permanent magnets. Platinum–nickel alloys, with as much as 20% nickel, are noted for high strength. With 5% nickel, for example, tensile strength of the annealed alloy is about 621 MPa, and with 15%, it increases to 896 MPa. Strength almost doubles with appreciable cold work.

Platinum–Rhenium

These alloys are efficient catalyst for reforming operations on aromatic compounds. The platinum alloys have lower electric conductivity than pure platinum, but are generally harder and more wear resistant, and have high melting points. A platinum–rhenium alloy with 10% rhenium has an electrical conductivity of only 5.5% that of copper compared with 16% for pure platinum. Its melting point is 1850°C, and the Rockwell T hardness of the cold-rolled metal is 91 compared with 78 for cold-rolled platinum.

Platinum–Tungsten

These alloys, with 2%–8% tungsten, have been used for aircraft engine spark plug electrodes, radar-tube grids, strain gauges, glow wires, switches, and heating elements. Tungsten markedly increases electrical resistivity while decreasing the temperature coefficient of resistivity. It also substantially increases tensile strength—to 896 MPa for platinum (8% tungsten alloy in the annealed condition)—and tensile strength more than doubled with appreciable cold work.

Platinum Black

(1) A finely divided form of platinum powder of a dull black color, usually, but not necessarily, produced by reduction of salts in an aqueous solution. (2) A very effective catalyst of some chemical reactions.

Platinum Group Metals

The platinum group metals—ruthenium, rhodium, palladium, osmium, iridium, and platinum—are found in the second and third long period in group VIII of the periodic table. Platinum and palladium are the most abundant of the group although all are generally found together.

The outstanding characteristics of platinum, the most important member of the group, are its remarkable resistance to corrosion and chemical attack, high melting point, retention of mechanical strength, and resistance to oxidation in air, even at very high temperatures. These qualities, together with the ability of the metal to greatly influence the rates of reaction in a large number of chemical processes, are the basis of nearly all its technical applications. The other five metals of the platinum group are also characterized by high melting points, good stability, and resistance to corrosion. Addition of these metals to platinum forms a series of alloys that provide a wide range of useful physical properties combined with the high resistance to corrosion that is characteristic of the parent metals.

Platinum (Pt)

When heated to redness, platinum softens and is easily worked. It is virtually nonoxidizable and is soluble only in liquids generating free chlorine, such as aqua regia. At red heat, platinum is attacked by cyanides, hydroxides, sulfides, and phosphides. When heated in an atmosphere of chlorine, platinum volatilizes and condenses as the crystalline chloride. Reduction of platinum chloride with zinc gives platinum black, which has a high adsorptive capacity for hydrogen. Platinum sponge is finely divided platinum.

Palladium (Pd)

Palladium is silvery white, very ductile, and slightly harder than platinum. It is readily soluble in aqua regia and is attacked by boiling nitric and sulfuric acids. Palladium has a remarkable ability to occlude large quantities of hydrogen. When properly alloyed, it can be used for the commercial separation and purification of hydrogen. Palladium and platinum can both be worked by normal metalworking processes.

Iridium (Ir)

This is the most corrosion-resistant element known. It is a very hard, brittle, tin-colored metal with a melting point higher than that of platinum. It is soluble in aqua regia only when alloyed with sufficient platinum. Iridium has its greatest value in platinum alloys where it acts as a hardening agent. By itself, it can be worked only with difficulty.

Rhodium (Rh)

Rhodium serves an important role in applications with high temperatures up to 1649°C. Platinum–rhodium thermocouple wire makes possible high-temperature measurement with great accuracy. Rhodium and rhodium alloys are used in furnace windings and in crucibles at temperatures too high for platinum. It is a very hard, white metal and is workable only under certain conditions and then with difficulty. Applied to a base metal by electroplating, it forms a hard, wear-resistant, permanently brilliant surface. Solubility is light even in aqua regia.

Ruthenium (Ru)

Ruthenium is hard and brittle with a silver-gray luster. Its tetroxide is very volatile and poisonous. When alloyed with platinum, its effect on hardness and resistivity is the greatest of all the metals in the group. It is unworkable in the pure state.

Osmium (Os)

This element has the highest specific gravity and melting point of the platinum metals. It oxidizes readily when heated in air to form a very volatile and poisonous tetroxide. Application has been predominantly in the field of catalysis. As a metal, it is also practically unworkable.

Plenum

The space between the inside wall of the constricting nozzle and the electrode in a plasma arc torch used for welding, cutting, or thermal spraying.

Plied Yarn

Yarn for reinforced plastics made by collecting two or more single yarns. Normally, the yarns are twisted together, though sometimes they are collected without a twist.

Plowing

(1) In tribology, the formation of grooves by *plastic deformation* of the softer of two surfaces in relative motion. (2) Deep grooving by severe gouging and usually involving significant local mechanical deformation.

Plug

(1) A rod or mandrel over which a pierced tube is forced. (2) A rod or mandrel that fills a tube as it is drawn through a die. (3) A punch or mandrel over which a cup is drawn. (4) A protruding portion of a die impression for forming a corresponding recess in the forging. (5) A false bottom in a die. (6) A short mandrel over which a tube is drawn in the plug drawing process, sizing the bore at the same time as the die sizes the exterior. The plug may be retained in the die by a small mandrel in the tube bore or it may be designed to self-locate in position termed a *floating plug*. See also *tube making*.

Plug Corrosion

See *dezincification*.

Plug Tap

A tap with *chamfer* extending from 3 to 5 threads.

Plug Weld

A circular weld made through a hole in one member of a lap or tee joint. Neither a fillet-welded hole nor a spot weld is to be construed as a plug weld. The hole may be partially or completely filled with weld metal.

Plug-Assist Forming

A *thermoforming* process in which a plug or male mold is used to partially preform the plastic part before forming is completed using vacuum or pressure.

Plumbage

A special quality of powdered graphite used to coat molds and, in a mixture of clay, to make crucibles and bulk items.

Plumber's Solder

An alloy of about one-third tin, two-thirds lead. It solidifies over a wide range, 250°C–183°C, so during cooling, it has a long pasty stage allowing it to be wiped to form a smoothly curved surface. See *soft solder*.

Plunge Grinding

Grinding wherein the only relative motion of the wheel is radially toward the work.

Plunge Milling

Machining using a milling cutter that cuts only on its end face rather than as it traverses.

P

Plunger

Ram or piston that forces molten metal into a die in a *die-casting* machine. Plunger machines are those having a plunger in continuous contact with molten metal. See *cold chamber machine* and *hot chamber machine*.

Plus Mesh

The powder sample retained on a screen of stated size, identified by the retaining mesh number. See also *sieve analysis* and *sieve classification*.

Plus Sieve

The portion of a sample of a granular substance (such as metal powder) retained on a standard sieve of specified number. Contrast with *minus sieve*. See also *sieve analysis* and *sieve classification*.

Plutonium

One of the man-made transuranic elements. It is radioactive with a half-life of 24,000 years and is toxic. Its applications are largely confined to nuclear power and weapons.

Ply

A single layer in a *laminate*. In general, fabrics or felts consisting of one or more layers. Yarn resulting from a twisting operation (e.g., three-ply yarn consists of three strands of yarn twisted together). In *filament winding*, a ply is a single pass (two plies forming one layer).

Plymetal

Sheet consisting of bonded layers of dissimilar metals.

Plywood

Plywood is a term generally used to designate glued wood panels made up of layers, or plies, with the grain of one or more layers at an angle, usually 90°, with the grain of the other. The outside plies are called faces or face and back, the center plies are called the core, and plies immediately below the face and back, laid at right angles to them, are called the crossbands.

The core may be veneer, lumber, or various combinations of veneer and lumber, the total thickness may be less than 1.5 mm or more than 76 mm; the different plies may vary as to number, thickness, and wood species. Also, the shape of the members may vary. The crossbands and their arrangement generally govern both the properties (particularly warping characteristics) and uses of all such constructions.

Plywood is an outgrowth of the laminated wood known as veneer, which consists of an outside sheet of hardwood glued to a base of lower-cost wood. The term *veneer* actually refers only to the facing layer of selected wood, used for artistic effect or for economy in the use of expensive woods. Veneers are generally marketed in strip form and thicknesses of less than 0.32 cm in mahogany, oak, cedar, and other woods. The usual purpose of plywood now is not aesthetic but to obtain high strength with low weight. The term *laminated wood* generally means heavier laminate for special purposes, and such laminates usually contain a heavy impregnation of bonding resin that gives them more of the characteristics of the resin than of the wood.

Composition

The composition of a plywood panel is generally dependent on the end use for which it is intended. The number of plywood constructions is almost endless when one considers the number of wood species available, the many thicknesses of wood veneers used in the outer plies or cores, the placement of the adjacent plies, the type of adhesives and their qualities, various manufacturing processes, and more technical variations.

Conventional plywood generally consists of an odd number of plies with the grains of the alternate layers perpendicular to each other. The use of an odd number permits an arrangement that gives a substantially balanced effect; that is, when three plies are glued together with the grain of the outer two plies at right angles to that of the center ply, the stresses are balanced and the panel tends to remain flat with changes in moisture content. These forces may be similarly balanced with five, seven, or some other uneven number of plies. If only two plies are glued together with the grain of one ply at right angles to the other, each ply tends to distort the other when changes in moisture content occur; cupping will result.

Low-cost plywoods may be bonded with starch pastes, animal glues, or casein and are not water resistant, but are useful for boxes and for interior work. Waterproof plywood for paneling and general construction is now bonded with synthetic resins, but when the plies are heavily impregnated with the resin and the whole cured into a solid sheet, the material is known as a hardboard or as a laminated plastic rather than a plywood.

Grades and Types

Broadly speaking, two classes of plywood are available—hardwood and softwood. Most softwood plywood is composed of Douglas fir, but western hemlock, white fir, ponderosa pine, redwood, and other wood species are also used. Hardwood plywood is made of many wood species.

Various grades and types of plywood are manufactured. “Grade” is determined by the quality of the veneer and “type” by the moisture resistance of the glue line. For example, there are two types of Douglas fir plywood—interior and exterior. The interior type is expected to retain its form and strength properties when occasionally subjected to wetting and drying periods. It is commonly bonded with urea–formaldehyde resin adhesives. On the other hand, the exterior type is expected to retain its form and strength properties when subjected to cyclic wetting and drying and to be suitable for permanent exterior use. It is commonly bonded with hot-pressed phenolic resin glues.

For construction purposes, where plywood is employed because of its unit strength and nonwarping characteristics, the plies may be of a single type of wood and without a hardwood face. The Douglas Fir Plywood Association sets up four classes of construction plywood under general trade names. Plywall is plywood in wallboard grade; Plypanel is plywood in three standard grades for general uses; Plyscord is unsanded plywood with defects plugged and patched on one side; and Plyform is plywood in a grade for use in concrete forms.

The bulk of commercial plywood comes within these classes; the variations are in the type of wood used, the type of bonding adhesive, or the finish. Each wood, for example, is a paneling plywood with the face wire brushed to remove the soft fibers and leave the hard grain for two-tone finish. Paneling plywoods with faces of mahogany, walnut, or other expensive wood have cores of lower-cost woods, but the woods of good physical qualities are usually chosen.

Engineering Properties

The mechanical and physical properties of plywood are dependent upon the particular construction employed. Plywood may be designed for beauty, durability, rigidity, strength, cost, or many other properties. With practically an unlimited variety of constructions to choose from, there is a wide range of differing characteristics in any given plywood panel. Most important among properties are the following:

High Strength–Weight Ratio

Perhaps the most notable feature of plywood is its high strength–weight ratio. Plywood is given special consideration whenever lightness and strength are desired. Plywood is widely used for concrete form work, floor underlayment, roof decks, siding, and many other applications because of its high strength–weight ratio. A comparison between birch plywood and other structural materials shows that its strength–weight ratio was 1.52 times that of 100,000 lb test heat-treated steel and 1.36 times that of 10,000 lb test aluminum.

Bending Properties

A most desirable characteristic of plywood is its flatness, but it can and will support substantial curvatures without appreciable loss of strength. Standard construction plywood can be bent or shaped to nominal radii and held in place with adhesives, nails, screws, or other fixing methods.

The radius of curvature to which a panel can be formed varies with panel thickness and the species of wood employed in the panel construction. The arc of curvature is limited by the tension force in the outer plies of the convex perimeter and by the compression forces in the outer plies of the concave perimeter.

Waterproof plywood, soaked or steamed before bending, exhibits approximately 50% greater flexibility than panels bent when dry.

Resistant to Splitting

Because plywood has no line of cleavage, it cannot split. This is an exceptional property when one considers its effect on fastening. The crisscross arrangement of wood plies in plywood construction develops extraordinary resistance to pull-through of nail or screw heads.

Resistance to Impact

The absence of a cleavage line has a pronounced effect on the impact resistance of plywood. Plywood will fracture only when the impact force is greater than the tensile strength of the wood fibers in the panel composition. Under an impact force, the side of the panel opposite the impact point will rupture along the long grain fiber followed by successive shattering of the various plies. Splintering usually does not take place because pressure is dispersed throughout the panel at the point of impact. Under similar conditions, solid lumber will show complete rupture.

Beauty

Plywood has certain intrinsic qualities that add much to any structure or construction in which it is used. Because of improved modern methods of manufacture, there is practically no limit to the decorative potential of plywood.

The entire range of fine woods is at the designer's disposal; they vary in shade from golden yellow to ebony, from pastels to reds and browns. The use of bleaches, toners, and stains in manufacturing procedures gives the designer even greater latitude with respect to design freedom.

The fine woods employed in the manufacture of plywood offer warmth and charm to any decorative scheme because the surface of the wood variously absorbs, reflects, and refracts light rays, giving the wood pattern depth and making it restful to the eye. This phenomenon accounts for the play of color and pattern when a plywood panel is viewed from different angles.

Dimensional Stability

The absorption of water causes wood to swell, and this movement is much greater across the grain than along the grain. The alternating layers of veneers in standard plywood construction inhibit this cross-grain movement because the cross-grain weakness is reinforced by the long-grain stability. Therefore, the dimensional stability of a plywood panel can be controlled by controlling its moisture content. In the field, this control can be achieved by applying coatings such as paints, lacquers, and sealers of various types.

Thermal Insulating Qualities

The thermal insulating qualities of plywood are the same as those of the wood of which it is composed.

The use of plywood as an insulating material can be attributed to two factors: (1) the use of large sheets reduces the numbers of cracks and joints and thereby inhibits leakage; and (2) the resistance of plywood to moisture vapor transmission stabilizes the moisture content of the trapped air and maintains its insulating qualities.

Fire Resistance

Fire-resistant plywood is manufactured by impregnating the core stock with a salt solution, which, upon evaporation, leaves a salt deposit in the wood. Plywood or wood treated in this manner will not support combustion but will char when heated beyond the normal charring point of the wood.

Nonimpregnated plywood can be made fire resistant by applying surface coatings such as intumescent paint and chemicals such as borax. An intumescent paint has a silicate of soda base that bubbles or intumesces in the presence of heat, thus forming a protective coating. At high temperatures, borax releases a gas such as carbon dioxide, which blankets the fire. It must be noted that fire-resistant coatings are effective only in direct ratio to their thickness. Highly resistant plywood can be manufactured by using an incombustible core such as asbestos.

Resistance to Borers

Plywood panels are subject to attack by borers to the same extent as the wood species of which they are composed, but phenol formaldehyde resin glue lines are fairly effective barriers against further penetration. Panels may also be treated with pentachlorophenol for increased resistance to these pests.

Fatigue Resistance

Plywood has the same resistance to fatigue as the wood of which it is composed.

Fabrication

The fact that almost anyone can use plywood has contributed greatly to its wide acceptance in many varied applications. The utilization of plywood does not require special tools, special skills, or safeguards,

P

and practically anyone capable of handling a saw and hammer can make use of its inherent engineering properties.

Since plywood does not exhibit the typical cross-grain weakness of lumber, it can very often be used in place of lumber for various applications. For example, 0.312 mm thick plywood replaces conventional 0.750 mm sheathing; 0.250 mm plywood can be used for interior wall paneling without sheathing; and 0.375 mm plywood can be used for shipping containers, furniture, and case goods instead of 0.750 mm lumber. The use of the thinner plywood reduces weight and bulkiness and is less fatiguing for tradespeople to handle. The use of large plywood sheets instead of narrow boards also reduces the amount of cutting, fitting, and fastening involved in a particular job.

Plywood is especially adaptable to the portable power-driven saws, drills, and automatic hammers normally used on production or construction jobs. Multiple cutting with band saws may be done with assurance because even the thinnest plywood has strength in all directions, and the danger of splitting or chipping is reduced to a minimum. This quality is particularly important when fine fitting is required.

Whenever plywood is employed in a structure, fewer and smaller fastenings can be specified because consideration need be given only to the holding power of the fastener and the tensile strength of the fastening itself.

Available Forms, Sizes, and Shapes

Plywood is available in practically any size, but the 1.2 × 2.4 m panel has become the standard production unit of the industry. Larger panels usually demand a price premium and are available on special order. Panels with continuous cores and faces can be produced in one piece up to 4 m long.

Oversize panels up to 2.4 m in width and of unlimited length can be manufactured by scarf jointing. (A scarf is an angling joint, made either in veneers or plywood, where pieces are spliced or lapped together. The length of the scarf is usually 12–20 times the thickness. When properly made, scarf joints are as strong as the adjacent unspliced material.)

Decorative plywood is now commercially available with a plant-applied finish. Prefinished wall paneling is supplied with a finish varying from offset printing to polyester film.

General Fields of Application

There are many uses and applications for plywood in industry today. Owing to the wide diversity of plywood applications, only the more prominent ones are mentioned here:

Architectural	Marine construction
Aviation	Mock-ups, models
Boatbuilding	Paddles
Building construction	Panel boards
Cabinet work	Patterns
Concrete forms	Prefabrication
Containers, cases	Remodeling
Die boards	Sheathing
Display	Signs
Fixtures	Sporting goods
Floor underlayment	Tabletops
Furniture	Toys
Hampers	Trays
Luggage	Truck floors, bodies
Machine bases	Wall paneling

P/M

The acronym for *powder metallurgy*.

PMMA

See *polymethyl methacrylate*.

PMR Polyimides

A novel class of high-temperature-resistant polymers. PMR represents in situ polymerization of monomer reactants. See also *polyimide*.

Pneumatic Press

A press that uses air or a gas to deliver the pressure to the upper and lower rams.

Pocket

In a *rolling-element bearing*, the portion of the case that is shaped to receive the rolling element. Compare with *oil pocket*.

Pocket Thrust Bearing

An externally pressurized thrust bearing having three or more hydrostatic pads with central relieved chambers of pocket supplied with pressurized oil.

Point Angle

In general, the angle at the point of a cutting tool. Most commonly, the included angle at the point of a twist drill, the general-purpose angle being 118°.

Point Defects

Irregularities in the crystal lattice that affect only a single site or local area, for example, a vacancy or a foreign atom, either substitutional or interstitial.

Point Estimate

The estimate of a *parameter* given by a single statistic.

Pointing

(1) Reducing the diameter of wire, rod, or tubing over a short length at the end by swaging or hammer forging, turning, or squeezing to facilitate entry into a drawing die and gripping in the drawhead. (2) The operation in automatic machines of chamfering or rounding the threaded end or the head of a bolt.

Poise (P)

The centimeter–gram–second (cgs) unit of dynamic viscosity (1 P = 0.1 Pa · s).

Poiseuille

The meter–kilogram–second (mks) or Système International d'Unités unit of dynamic viscosity (1 Pl = 10 P).

Poison Gas

Poison gases are classified according to their main effect on the human system, but one gas may have several effects. They are grouped as follows: *lethal gases*, intended to kill, such as phosgene; *lachrymators*, or *tear gases*, which have a powerful irritating effect on the eyes, causing temporary blindness and swelling of the eyes with a copious flow of tears; *vesicants*, or skin blisters, such as lewisite and mustard gas; *sternutatory gases*, which induce sneezing, and *camouflage gases*, which are harmless, but cause soldiers to suffer the inconvenience of wearing gas masks and thus reduce their morale. Some of the gases have a sour, irritating odor and are also classified as *harassing agents*. Gases are also sometimes designated as *casualty agents* and further subdivided into persistent and nonpersistent. A *systemic gas* is one that interferes with one phase of the system, such as carbon monoxide, which paralyzes the respiratory function of the blood. A *labyrinthic gas*, which contains dichloromethyl ether, is one that affects an organ of the body, which affects the ears.

Poison Gases

Substances employed in chemical warfare for disabling people and in some cases used industrially as fumigants. They are all popularly called gases, but many are liquids or solids. Normally, information on military gases is kept secret, but the tear gases used by police are also poisonous, often causing serious damage to the eyes, throat, and lungs. *Anesthetic gases* have not been used so far in chemical warfare, but are used in medicine. One of the simplest of these, *nitrous oxide*, N_2O , called *laughing gas*, produces a deep sleep. *Fluothane*, or *ethyl fluoride*, is a volatile liquid like ether, but is nonexplosive, and it is used to replace ether in surgery.

Poisson's Ratio

The ratio of transverse strain to longitudinal strain. When a metal is pulled in tension, it extends longitudinally and contracts in the transverse direction. The ratio of the two strains is between 0.25 and 0.5 for elastic deformation and 0.5 and 0.5 for plastic deformation.

Poke Welding

Same as *push welding*.

Polar Bonding

Same as *ionic bonding*; see *interatomic bonding*.

Polar Winding

In filament winding of composites, a winding in which the filament path passes tangent to the polar opening at one end of the chamber and tangent to the opposite side of the polar opening at the other end. A one-circuit pattern is inherent in the system. See also *helical winding*.

Polarimeter

An instrument used to determine the rotation of the plane of polarization of plane polarized light when it passes through a substance; the light is linearly polarized by a polarizer (such as a *Nicol prism*), passes through the material being analyzed, and then passes through an analyzer.

Polariscope

Any of several instruments used to determine the effects of substances on polarized light, in which linearly or elliptically polarized light passes through the substance being studied, and then through an analyzer.

Polarity (Welding)

See *direct current electrode negative*, *direct current electrode positive*, *straight polarity*, and *reverse polarity*.

Polarization

(1) The change from the open-circuit electrode potential as the result of the passage of current. (2) A change in the *potential* of an electrode during electrolysis, such that the potential of an *anode* becomes more noble, and that of a *cathode* more active, than their respective reversible potentials. Often accomplished by formation of a film on the electrode surface. (3) In the context of light and optics, polarized light is comprised of waves in a single plane as opposed to normal light that has waves in all planes.

Polarization Admittance

The reciprocal of *polarization resistance* (dI/dE).

Polarization Curve

A plot of *current density* versus *electrode potential* for a specific electrode–electrolyte combination.

Polarization Resistance

The slope (dE/di) at the *corrosion potential* of a potential (E)/current density (i) curve. Also used to describe the method of measuring corrosion rates using the slope.

Polarized Light Illumination

A method of illumination in which the incident light is plane polarized before it impinges on the specimen. See also *optical microscope*.

Polarizer

In an optical microscope, a *Nicol prism*, polarizing film, or similar device into which a normal light passes and from which polarized light emerges.

Polarizing Element

A general term for a device for producing or analyzing plane-polarized light. It may be a *Nicol prism*, some other form of calcite prism, a reflecting surface, or a polarizing filter. See also *polarizer*.

Polarography

An electroanalytical technique in which the current between a dropping mercury electrode (DME) and a counterelectrode

P

(both of which are immersed in electrolyte) is measured as a function of the potential difference between the DME and a reference electrode.

Poldi Test

A simple handheld hardness testing device in which a 10 mm diameter, hard steel ball is located in a head piece so as to register on the component surface to be tested and, at the same time, on the surface of a square bar of known hardness. The head is struck causing simultaneous indentations on the bar and on the test surface. The two indentations are then measured and the results read against charts to provide a measure of hardness of the component.

Pole

(1) A means of designating the orientation of a crystal plane by stereographically plotting its normal. For example, the North Pole defines the equatorial plane. Either of the two regions of a permanent magnet or electromagnet where most of the lines of induction enter or leave.

Pole Figure

A stereoscopic projection of a polycrystalline aggregate showing the distribution of poles, or plane normals, of a specific crystalline plane, using specimen axes as reference axes. Pole figures are used to characterize preferred orientation in polycrystalline materials. See *orientation*.

Pole Piece

The magnetic material, forming the extension of a magnet, which is intended to concentrate and direct the magnetic flux.

Polepiece

In reinforced plastics, the supporting part of the mandrel used in filament winding, usually on one of the axes of rotation.

Poling

A step in the fire refining of copper to reduce the oxygen content to tolerable limits by covering the bath with coal or coke and thrusting green wood poles below the surface. There is a vigorous evolution of reducing gases, which combine with the oxygen contained in the metal.

Polished Surface

A surface prepared for metallographic inspection that reflects a large proportion of the incident light in a specular manner. See also *polishing* (4).

Polishing

(1) A surface-finishing process for ceramics and metals utilizing successive grades of abrasive. (2) Smoothing metal surfaces, often to a high luster by rubbing the surface with a fine abrasive, usually contained in a cloth or other soft lap. Results in microscopic flow of some surface metal together with actual removal of a small amount of surface metal. (3) Removal of material by the action of

abrasive grains carried to the work by a flexible support, generally either a wheel or a coated abrasive belt. (4) A mechanical, chemical, or electrolytic process or combination thereof used to prepare a smooth, reflective surface suitable for microstructural examination that is free of artifacts or damage introduced during prior sectioning or grinding. See also *electrolytic polishing* and *electropolishing*.

Polishing Artifact

A false structure introduced during a polishing stage of a surface-preparation sequence.

Polishing Lap, Stick, Pad, etc.

The device or structure on which a polishing medium is carried to polish some component.

Polishing Rate

The rate at which material is removed from a surface during polishing. It is usually expressed in terms of the thickness removed per unit of time or distance traversed.

Polishing Wear

An extremely mild form of wear for which the mechanism has not been clearly identified, but that may involve extremely fine-scale abrasion, plastic smearing of micro-asperities, and/or tribochemical material removal.

Polonium

Polonium (symbol Po) is a rare metallic element belonging to the group of radioactive metals, but emitting only alpha rays. The melting point of the metal is about 254°C. It is used in meteorological stations for measuring the electrical potential of the air. Polonium-plated metal in strip and rod forms has been employed as a static dissipator in textile-coating machines. The alpha rays ionize the air near the strip, making it a conductor and drawing off static electric charges. Polonium-210 is obtained by irradiating bismuth; 45 kg yields 1 g of polonium-210. It is used as a heat source for emergency auxiliary power such as in spacecraft. The metal is expensive, but can be produced in quantity from bismuth.

Poly-

As a prefix, it means many. In most cases, it refers to various types of polymer.

Polyacrylate Resin

Useful polymers can be obtained from a variety of acrylic monomers, such as acrylic in methacrylic acids, and their salts, esters, amides, and the corresponding nitriles. Polymethyl methacrylate (PMMA), polyethylene acrylate, and a few other derivatives are the most widely used.

PMMA is a hard, transparent polymer with high optical clarity, high refractive index, and good resistance to the effects of light

and aging. It and its copolymers are useful for lenses, signs, indirect lighting fixtures, transparent domes and skylights, dentures, and protective coatings.

Solutions of PMMA and its copolymers are useful as lacquers. Aqueous latexes formed by the emulsion polymerization of methyl methacrylate with other monomers are useful as water-based paints and in the treatment of textiles and leather.

Polyethyl acrylate is a tough, somewhat rubbery product. The monomer is used mainly as a plasticizing or softening component of copolymers. Ethyl acrylate is usually produced by the dehydration and ethanolysis of ethylene cyanohydrin.

Modified acrylic resins with high impact strength can be prepared. Blends or "alloys" with polyvinyl chloride are used for thermoforming impact-resistant sheets.

Methyl methacrylate is of interest as a polymerizable impregnant for concrete: usually a cross-linking acrylic monomer is also incorporated.

Polymers of methyl acrylate or acrylamide are water soluble and useful for sizes and finishes. Addition of polyacrylate to petroleum lubricating oil improves the flowing properties of the oil at low temperatures and the resistance to thinning at high temperatures.

Polyacrylic Rubber

The first types of polyacrylic rubbers were proposed as oxidation-resistant elastomeric materials. Chemically, they were polyethyl acrylate, and a copolymer of ethyl acrylate and 2-chloroethyl vinyl ether.

The development of polyacrylic rubbers was accelerated by the interest expressed throughout the automotive industry in the potential applications of this type of polymer in special types of seals. An effective seal for today's modern lubricants must be resistant not only to the action of the lubricant but to increasingly severe temperature conditions. It must also resist attack of highly active chemical additives that are incorporated in the lubricant to protect it from deterioration at extreme temperature.

Polyacrylic rubber compounds were developed to provide a rubber part that would function in applications where oils and/or temperatures as high as 204°C would be encountered. These were also very resistant to attack by sulfur-bearing chemical additives in the oil. These properties have resulted in general use of polyacrylic rubber compounds for automotive rubber parts as seals for automatic transmission fluids and extreme-pressure lubricants.

Polyacrylic rubber will prove most useful in fields where these special properties are used to the maximum. It is recommended for products such as automatic transmission seals, extreme-pressure lubricant seals, searchlight gaskets, belting, rolls, tank linings, hose, O-rings and seals, white- or pastel-colored rubber parts, solution coatings, and pigment binders on paper, textiles, and fibrous glass.

Curing

A typical polyacrylic rubber, such as the copolymer of ethyl acrylate and chloroethyl vinyl ether, is supplied as a crude rubber in the form of white sheets having a specific gravity of approximately 1.1. It may be mixed and processed according to conventional rubber practice.

However, polyacrylic rubber is chemically saturated and cannot be cured in the same manner as conventional rubbers. Sulfur and sulfur-bearing materials act as retarders of cure and function as a form of age resistor in most formulations. Polyacrylic rubber is cured with amines; "Trimene Base" and triethylene tetramine are

most widely used. Aging properties may be altered by balancing the effect of the amine and the sulfur.

Like other rubber polymers, reinforcing agents such as carbon black or certain white pigments are necessary to develop optimum physical properties in a polyacrylic rubber vulcanizate. Selection of the pigments is more critical in that acidic materials, which would react with the basic amine curing systems, must be avoided. The SAF (Super Abrasion Furnace), ASTM designation N110 or FEF (Fast Extruding Furnace), ASTM designation N550 carbon blacks are most widely used, while hydrated silica or precipitated calcium silicate are recommended for light-colored stocks.

Typical curing temperatures are from 143°C to 166°C and cure times of 10–45 min depending on the thickness of the part. Polished, chromium-plated molds are recommended. For maximum overall physical properties, the cured parts should be tempered in an air oven for 24 h at 149°C.

Forming

To obtain smooth extrusions, more loading and lubrication are necessary than for molded goods, because of the inherent nerve of the polymer. Temperatures of 43°C in the barrel and 77°C on the die are recommended.

Generally, those compounds that extrude well are also good calendering stocks. Suggested temperatures for calendering are in the range of 37.8°C–54°C. Higher temperatures will result in sticking of the stock to the rolls. Under optimum conditions, 15 mil films may be obtained.

Polyacrylic rubber may be coated on nylon either by calendering or from solvent solution. It also has excellent adhesion to cotton and is often used as a solvent solution applied to cotton duck to be used as belting. Solvents generally used include methylethyl ketone, toluene, xylene, or benzene.

Polyacrylic rubber is most widely used in many types of seals because of its excellent resistance to sulfur-bearing oils and lubricants.

In general, polyacrylic rubber vulcanizates are resistant to petroleum products and animal and vegetable fats and oils. They will swell in aromatic hydrocarbons, alcohols, and ketones. Polyacrylic rubber is not recommended for use in water, steam, ethylene glycol, or alkaline media.

Laboratory tests indicate that polyacrylic vulcanizates become stiff and brittle at a temperature of –23°C. But in actual service, these same polyacrylic rubbers have been found to provide satisfactory performance at engine start-up and operation in oil at temperatures as low as –40°C.

For those applications requiring improvement in low-temperature brittleness by as much as –4.0°C and that can tolerate considerable sacrifice in overall chemical oil and heat resistance, a copolymer of butyl acrylate and acrylonitrile may be used.

Polyacrylonitrile (PAN)

A base material or precursor used in the manufacture of certain carbon fibers. PAN-based carbon fibers have a ribbonlike structure and possess high strength (400 GPa, or 10⁶ psi, tensile modulus).

Polyacrylonitrile (PAN) Resins

The PAN resins are hard, horny, relatively insoluble, and high-melting materials. PAN (*polyvinyl cyanide*) is used almost entirely in copolymers. The copolymers fall into three groups: fibers, plastics, and rubbers. The presence of acrylonitrile in a polymeric

P

composition tends to increase its resistance to temperature, chemicals, impact, and flexing.

Acrylonitrile is generally prepared by several methods, including the catalyzed addition of hydrogen cyanide to acetylene. The polymerization of acrylonitrile can be readily initiated by means of the conventional free-radical catalysts such as peroxides, by irradiation, or by the use of alkaline metal catalysts. Although polymerization in bulk proceeds rapidly to be commercially feasible, satisfactory control of a polymerization or copolymerization may be achieved in suspension and in emulsion, and in aqueous solutions from which the polymer precipitates. Copolymers containing acrylonitrile may be fabricated in the manner of thermoplastic resins.

The major use of acrylonitrile is in the form of fibers. By definition, an acrylic fiber must contain at least 85% acrylonitrile; a mod-acrylic fiber may contain less than 35%–85% acrylonitrile. The high strength; high softening temperature; resistance to aging, chemicals, water, and cleaning solvents; and the soft wood-like feel of fabrics have made the product popular for many uses such as sails, cordage, blankets, and various types of clothing. Commercial forms of the fiber probably are copolymers containing minor amounts of other vinyl derivatives, such as vinyl pyrrolidone, vinyl acetate, maleic anhydride, or acrylamide. The comonomers are included to produce specific effects, such as improvement of dyeing qualities.

Copolymers of vinylidene chloride with small proportions of acrylonitrile are useful as tough, impermeable, and heat-sealable packaging films.

Copolymers for extensive use are made of acrylonitrile with butadiene, often called NBR (formerly Buna N) rubbers, which contain 15% acrylonitrile. Minor amounts of other unsaturated esters, such as ethyl acrylate, which yield carboxyl groups on hydrolysis, may be incorporated to improve the curing properties. The NBR rubbers are resistant to hydrocarbon solvents such as gasoline and abrasion and in some cases show high flexibility at low temperatures.

In the 1960s, development of blends and interpolymers of acrylonitrile-containing resins and rubbers represented a significant advance in polymer technology. The products, usually called *acrylonitrile, butadiene, and styrene (ABS) resins*, typically are made by blending acrylonitrile–styrene copolymers with a butadiene–acrylonitrile rubber or by interpolymerizing polybutadiene with styrene and acrylonitrile. Specific properties depend on the proportions of the comonomer, on the degree of graftings, and on molecular weight. In general, the ABS resins combine the advantages of hardness and strength of the vinyl resin component with toughness and impact resistance of the rubbery component. Certain grades of the ABS resin are used for blending with brittle thermoplastic resins such as polyvinyl chloride to improve impact strength.

The combination of low cost, good mechanical properties, and ease of fabrication by a variety of methods, including typical metal working methods such as cold stamping, led to the rapid development of new uses for ABS resins. Applications include products requiring high impact strength, such as pipe, and sheets for structural uses, such as industrial duct work and components of automobile bodies. ABS resins are also used for housewares and appliances, because of their ability to be electroplated for decorative items in general.

Polyamide Plastic

See *nylon plastics* and *polyamides*.

Polyamide-Imide Resins

A family of polymers based on the combination of trimellitic anhydride with aromatic diamines. In the uncured form (ortho-amic

acid), the polymers are soluble in polar organic solvents. The imide linkage is formed by heating, producing an infusible resin with thermal stability up to 260°C (500°F). These resins, which also include graphite- (powder and fiber) and glass-fiber-reinforced grades, are used in the automotive (friction and wear parts), aerospace (fasteners and housings), and electronic (connector industries) applications.

Polyamides (PA)

PA resins are thermoplastic polymers that are most commonly regarded as being synonymous with nylons, that is, synthetic polymers that contain an amide group, $-\text{CONH}-$, as a recurring part of the chain. Nylons are made from diamines and dibasic acids, ω -amino acids, or lactams. Nylons are commonly identified by numbers corresponding to the number of C atoms in the monomers. Thus, resins are known as nylon 6/6, nylon 11, and nylon 6, respectively. The molecular weights of nylons range from 11,000 to 34,000. They are usually semicrystalline polymers with melting points in the range of 175°C–300°C (350°F–570°F).

Nylon 6/6 and nylon 6 are the most important commercial products. Their melting points are 269°C and 228°C (516°F and 440°F), respectively. Other commercial nylons are 6/9, 6/10, 6/12, 11, 12, and 4/6. The more C atoms, that is, the lower the concentration of amide groups, the lower the melting point. Nylons are very readily modified by the use of monomer mixtures leading to copolymers. These are normally less crystalline, more flexible, and more soluble than the previously mentioned homopolymers.

Additives are used in nylons to improve thermal and photolytic stability, facilitate processing, increase flammability resistance, increase lubricity, and generally improve whatever specific property is required for a specific application. Susceptibility to modification is an important asset. Fiber and mineral reinforcements are widely used. Blending with elastomeric modifiers has yielded nylons with improved toughness (impact strength).

Molded and extruded nylons are used in virtually every industry and market. Transportation represents the largest single market for nylons (~30% of the market). Applications for unreinforced materials include electrical connectors, wire jackets, and light-duty gears for windshield wipers and speedometers. Toughened nylons are used as stone shields and trim clips. Glass-reinforced nylons are used for engine fans, radiator headers, brake, and power-steering fluid reservoirs, as well as other uses. Mineral-reinforced resins are used for mirror housings. Nylons containing both glass and minerals are used as fender extensions. Nylons for electrical and electronic applications constitute about 11% of the market. Applications include plugs, connectors, relays, and antenna-mounting devices. Because of their excellent resistance to fatigue and repeated impact, nylons are widely used in industrial products such as unlubricated gears, bearings, and antifriction parts. Consumer products include toughened nylons for ski boots, ice and roller skate supports, racket sports equipment, kitchen utensils, and toys. Extruded nylon film is widely used for packaging meals and cheeses and for cook-in bags and pouches. Other applications include wiring cable jacketing, tubing used to convey fluids, and nylon filaments for paintbrush bristles, fishing lines, and sewing thread.

Polyamide-Imides (PAI)

PAIs are engineering thermoplastics characterized by excellent dimensional stability, high strength at high temperature, and good impact resistance. Molded parts can maintain structural integrity and continuous use at temperatures to 260°C.

PAI, produced and called *Torlon*, is available in several grades including a general-purpose, injection-molding grade; three polytetrafluoroethylene (PTFE)/graphite wear-resistant compounds; a 30% graphite-fiber-reinforced grade; and a 30% glass-fiber-reinforced grade. Additional grades are developed to meet special requirements.

Torlon resins are moldable on screw-injection-molding machines. Molds must be heated to 218°C, and the barrel and nozzle should be capable of being heated to about 371°C. High injection speed and pressure (136 MPa or greater) are desirable. Developing optimum physical properties in injection-molded or extruded parts requires postcuring through an extended, closely controlled temperature program gradually reaching 260°C. The specific time/temperature program depends on part configuration and thickness.

Properties

Room-temperature tensile strength of unfilled PAI is about 190 MPa and compressive strength is 213 MPa. At 232°C, tensile strength is about 61.2 MPa—as strong as many engineering plastics at room temperature—and continued exposure at 260°C for up to 8000 h produces no significant decline in tensile properties.

Flexural modulus of 36.5 MPa of the unfilled grade is increased, with graphite-fiber reinforcement, to 19,913 MPa. Retention of modulus at a temperature of 260°C is on the order of 80% for the reinforced grade. Creep resistance, even at high temperature and under load, is among the best of the thermoplastics; dimensional stability is extremely good.

PAI is extremely resistant to flame and has very low smoke generation. Reinforced grades have surpassed Federal Aviation Administration requirements for flammability, smoke density, and toxic gas emission.

Radiation resistance of PAI is good; tensile strength drops only about 5% after exposure to 10⁹ rad of gamma radiation. Chemical resistance is good, the resin being virtually unaffected by aliphatic and aromatic hydrocarbons, halogenated solvents, and most acid and base solutions. It is attacked, however, by some acids at high temperature, steam at high pressure and high temperature, and strong bases.

Torlon moldings absorb moisture in human environments or when immersed in water, but the rate is low, and the process is reversible. Parts can be restored to original dimensions by drying.

Polyaryl Sulfone

A thermoplastic resin consisting mainly of phenyl and biphenyl groups linked by thermally stable ether and sulfone groups. Its most outstanding property is resistance to high and low temperatures (from -240°C to 260°C, or -400°F to 500°F). It also has good impact resistance, resistance to chemical oils and most solvents, and good electrical insulating properties. It can be processed by injection molding, extrusion, compression molding, ultrasonic welding, and machining.

Polyarylates

These high-heat-resistant thermoplastics are derived from aromatic dicarboxylic acids and diphenols. When molded, they become amorphous, providing a combination of toughness, dimensional stability, high dielectric properties, and ultraviolet (UV) stability. Polyarylates have heat-deflection temperatures up to 175°C at 264 lb/in.². The resins can be injection molded, extruded, and

blow molded, and sheet can be thermoformed. These resins also are blended with other engineering thermoplastics and reinforcements. They have excellent dimensional and UV stability, electrical properties, flame retardants, and warp resistance.

Polyarylene Ether Benzimidazoles (PAEBI)

PAEBI polymers, developed at NASA-Langley in 1991, common by high-gloss transition temperature and optical transmission with inherent resistance to high-energy particles, especially atomic oxygen, thus being suitable for thermal control in harsh space environments, such as low earth orbit. Though reacting similarly to other plastics on initial exposure to atomic oxygen, PAEBI incorporates a phosphorus-oxygen linkage that subsequently forms an in situ protective coating, making the plastic more than 15 times as resistant as *Kapton* polyimide to erosion by atomic oxygen. The polymer is produced in the form of *TOR* and *TOR-LM castable films* by Triton Systems Inc. and, for thermal-control applications, can be metallized with aluminum, silver, or Inconel.

Polyaryletherketones (PAEK)

A glass-fiber-reinforced (PAEK) semicrystalline polymer has been designed into the sensor housing for a new conductivity-measuring cell.

Conductivity-measuring cells are used to determine the electrolytic conductivity of media in the food and pharmaceutical industries. The primary requirements for the cell are resistance to corrosive media and biocompatible surface quality to remain in compliance with U.S. and European hygienic requirements. The PAEK polymer is insoluble in all common solvents and can be immersed for thousands of hours at temperatures more than 250°C in steam or high-pressure water environments without significant degradation. The addition of glass fibers increases the chemical resistance of the base resin as well as mechanical strength at elevated temperatures. This definition is also germane to *polyetheretherketone*, *polyetherketone*, and *polyetherketoneketone*.

Polybenzimidazole (PBI)

A thermoplastic resin that is strong and stable, has a high molecular weight, and contains recurring aromatic units. The resin is produced by the high-temperature, melt condensation reaction of aromatic bis-ortho-diamines and aromatic dicarboxylates (acids, esters, or amides). Although a wide variety of PBIs have been synthesized, the most common is (2,2'-(*m*-phenylene)-5,5'-bibenzimidazole). Parts made from PBI are used in petrochemical, geothermal, chemical process, power generation, aerospace, and transportation markets.

PBI has been used in a variety of applications for the U.S. space program, including flight suits and other protective clothing, webbing, straps, and tethers. Research of raw materials and process development has continued, along with applications development that began in the 1960s and 1970s.

In 1983, commercial production of PBI fiber commenced. Today, PBI fiber has been used successfully in firefighters' gear, industrial protective clothing, fire-blocking layers for aircraft seats, braided pump packings, and other high-performance products. Research has continued to develop other forms of PBI. In addition to *Celazole* molded parts, these forms include polymer additives, films, fibrils, papers, microporous resin, sizing, and coatings.

P

Scientists say the material has no known melting point and can withstand pressures of up to 394 MPa. It also has demonstrated resistance to steam at 343°C.

Polybutylene Terephthalate

A member of the polyalkyleneterephthalate family that is produced by the transesterification of dimethyl terephthalate with butanediol by means of a catalyzed melt polycondensation. Properties include high strength, dimensional stability, low moisture absorption, good electrical characteristics, and resistance to heat and chemicals when suitably modified.

Polycarbonates

Polycarbonate resins offer a combination of properties that extends the usefulness and fields of application for thermoplastic materials. This relatively new plastic material is characterized by very high impact strength, superior heat resistance, and good electrical properties.

In addition, the low water absorption, high heat distortion point, low and uniform mold shrinkage, and excellent creep resistance of the material result in especially good dimensional stability. Of value for many applications are its transparency, shear strength, stain resistance, color ability and loss, oil resistance, machinability, and maintenance of good properties over a broad temperature range from less than -73°C to 132°C to 138°C. The fact that polycarbonate resin is self-extinguishing is important in many applications.

Polycarbonates are amorphous engineering thermoplastics that offer exceptional toughness over a wide temperature range. The natural resins are water-clear and transparent.

Polycarbonate resins are available in general-purpose molding and extrusion grades and in special grades that provide specific properties or processing characteristics. These include flame-resistant formulations as well as grades that meet Food and Drug Administration regulations for parts used in food-contact and medical applications. Other special grades are used for blow molding, weather and UV-resistance, glass-reinforcement, EMI, RFI, ESD-shielding, and structural-foam applications. Polycarbonate is also available in extruded sheet and film.

Composition

The polycarbonate name is taken from the carbonate linkage that joins the organic units in the polymer. This is the first commercially useful thermoplastic material that incorporates the carbonate radical as an integral part of the main polymer chain.

There are several ways polycarbonates can be made. One method involves a bifunctional phenol, bisphenol A, which combines with carbonyl chloride by splitting out hydrochloric acid to give a linear polymer consisting of bisphenol groups joined together by carbonate linkages. Bisphenol A, which is the condensation product of phenol and acetone, is the basic building block used also in the preparation of epoxy resins.

Other members of the polycarbonate family may be made by using other phenols and other ketones to modify the isopropylidene group or to replace this bridge entirely. Substitutions on the benzene ring offer further possibilities for variations.

Properties

Polycarbonate is a linear, low-crystalline, transparent, high-molecular-weight plastic. It is generally considered to be the toughest of all plastics. In thin sections, up to about 0.478 cm, its impact strength is as

high as 24 kg. In addition, polycarbonate is one of the hardest plastics. It also has good strength and rigidity and, because of its high modulus of elasticity, is resistant to creep. These properties, along with its excellent electrical resistivity, are maintained over a temperature range of about -170°C to 121°C. It has negligible moisture absorption, but it also has poor solvent resistance and, in a stressed condition, will craze or crack when exposed to some chemicals. It is generally unaffected by greases, oils, and acids. Polycarbonate plastics are easily processed by extrusion; by injection, blow, and rotational molding; and by vacuum forming. They have very low and uniform mold shrinkage. With a light transmission of almost 90% and high impact resistance, they are good glazing materials. They have more than 30 times the impact resistance of safety glass. Other typical applications are safety shields and lenses. Besides glazing, the high impact strength of polycarbonate makes it useful for air-conditioner housings, filter bowls, portable tool housings, marine propellers, and housings for small appliances and food-dispensing machines.

Humidity changes have little effect on dimensions or properties of molded parts. Even boiling water exposure does not change dimensions more than 0.30 mm/mm if the parts return to room temperature. Creep resistance is excellent throughout a broad temperature range and is improved by a factor of 2-3 in glass-reinforced compounds.

The insulating and other electrical characteristics of polycarbonate are excellent and almost unchanged by temperature and humidity conditions. One exception is arc resistance, which is lower than that of many other plastics.

Polycarbonates are generally unaffected by greases, oils, and acids. Nevertheless, compatibility with specific substances in a service environment should be checked with the resin supplier. Water at room temperature has no effect; the continuous exposure in hot (65°C) water causes gradual embrittlement. The resins are soluble in chlorinated hydrocarbons and are attacked by most aromatic solvents, esters, and ketones, which cause crazing and cracking in stressed parts. Grades with improved chemical resistance are available, and special coating systems can be applied to provide additional chemical protection.

Fabrication

Polycarbonate resin has been molded in standard injection equipment using existing molds designed for nylon, polystyrene, and acrylic, or other thermoplastic materials. Differences in mold shrinkage must be considered. And, in fabrication, the polycarbonate does have its own unique processing characteristics. Most important among these are the broad plastic range and high melt viscosity of the resin. Production runs in molds designed for nylon or acetal resin are not recommended.

Like other amorphous polymers, polycarbonate resin has no precise melting point. It softens and begins to melt over a range from 216°C to 227°C. Optimal molding temperatures lie above 271°C. The most desirable range of cylinder temperatures for molding the resin is in the area of 275°C to 316°C.

Mold design must take into consideration the high melt viscosity of the material. Large sprues, large full-round runners, and generous gates with short lands usually give best results.

Tab gating is good for filling large thin sections. The gate to the tab should be large.

In injection molding of polycarbonate, the following conditions are desirable:

1. *Heated molds:* Generally, hot water heat is adequate for heating molds, with typical molding temperatures ranging from 77°C to 93°C. Molds for large areas, thin sections,

or complex shapes or multiple cavity molds with long runners may require higher temperatures. Some molds have run best at 110°C–121°C.

2. *Cylinder temperatures:* The most usual cylinder temperature for molding polycarbonates is in the range of 275°C–316°C. Few parts require cylinder temperatures above 316°C. A heated nozzle and adequate molding temperature are helpful in keeping cylinder temperatures below 316°C. In most cases, rear cylinder temperatures higher than front cylinder temperatures give best results.
3. *Heated nozzle:* In general, nozzle temperature equal to front cylinder temperature gives good results.
4. *Adequate injection pressure:* Injection pressures used in molding polycarbonate resin range from 80 to 204 MPa. Most usual range is in the 103–136 MPa range. Typical pressure setting is 3/4 to full pressure capacity of the press.
5. *Fast fill time:* For most parts molded, a fast ram travel time has been found desirable for thick as well as thin sections. For very thick sections, it is better to utilize somewhat slower ram speed.

Polycarbonate must be well dried to obtain optimum properties in the molded part. For this reason, the resin is packaged in sealed containers.

Preheating pellets in the can to 121°C for 4–8 h and using copper heaters at 121°C are recommended for production operations to prevent moisture pickup.

Although polycarbonates are fabricated primarily by injection molding, other fabricating techniques may be used. Rod, tubing, shapes, film, and sheet may be extruded by conventional techniques. Films and coatings may be cast from solution. Parts can readily be machined from rod or standard shapes. Cementing, painting, metallizing, heat sealing, welding, machining operations, and other standard finishing operations may be employed. Film and sheet can be vacuum formed or cold formed.

Applications

The properties of polycarbonate resin make this new plastic suitable for a wide variety of applications. It is now being used in business machine parts, electrical and electronic parts, military components, and aircraft parts and is finding increasing use in automotive, instrument, pump, appliance, communication equipment, and many other varied industrial and consumer applications.

One of the applications is in molded coil forms, which take advantage of the electrical properties, heat and oxidation resistance, dimensional stability, and resistance to deformation under stress of the resin.

A transparent plastic with the heat resistance, the dimensional stability, and the impact resistance of polycarbonate resin has created considerable interest for optical parts, such as outdoor lenses, instrument covers, lenses, and lighting devices.

Housings make use of the impact resistance of the material and its attractive appearance and colorability. In many cases, also, heat resistance and dimensional stability are important.

An interesting application area for plastic materials is the use of polycarbonate resin for fabricating fasteners of various types. Such uses as grommets, rivets, nails, staples, and nuts are in production or under evaluation. The ability of polycarbonate parts to be cold-headed has developed considerable interest in rivet applications.

Terminal blocks, connectors, switch housings, and other electrical parts may advantageously be molded of polycarbonate resin to take advantage both of the electrical properties of the material and the unusual physical properties, which give strength and toughness

to the parts over a range of temperatures. Because of the heat resistance of polycarbonate, and the fact that it is self-extinguishing, molded parts can be used in current-carrying support applications.

Another application is in bushings, cams, and gears. Here, dimensional stability is important as is the high impact strength of the resin. Good physical properties over a broad temperature range, low water absorption, resistance to deformation under load, and resistance to creep suggest its use for many applications of this type. However, the resin has a higher coefficient of friction and a lower fatigue endurance limit than do some other plastics used in these types of applications. For this reason, it should not be considered a general-purpose gear and bearing material, but might be considered for applications subject to light loading or to heavier but intermittent loading.

In most heart bypass operations, the saphenous vein from a patient's leg replaces blocked blood vessels in the heart. The separate surgical procedure, performed during the heart bypass operation, involves removing the vein through a long incision. Following the surgery, patients frequently complain of ongoing leg pain, potentially leading to reduced mobility and delayed rehabilitation while the large incision heals.

A new generation of surgical instruments not only makes the procedure less invasive, it helps speed the patient's return to normal activities. The system uses endoscopic techniques to harvest the vein. This, in turn, requires smaller incisions. The potential benefits are less postoperative pain, fewer wound healing complications, minimal scarring, and quicker recovery.

The materials chosen for these applications have provided several significant benefits, and, from the medical side, the materials were biocompatible. The materials resist chemicals and withstand gamma sterilization. The balloon amount is made with polycarbonate. On the orbital dissection cannula, the end piece embodies a polycarbonate resin.

Polybutylenes

A group of polymers consisting of isotactic, stereoregular, highly crystalline polymers based on butylene 1. Their properties are similar to those of polypropylene and linear polyethylene, with superior toughness, creep resistance, and flexibility.

Polybutadiene Rubber

Polybutadiene may be prepared in several ways to yield different products. The method of polymerization can have a marked effect on polymer structure, which in turn controls the properties of the polymer and thus its ultimate end use.

Composition

When polybutadiene is made, the butadiene molecule may enter the polymer chain by either 1,4-addition or 1,2-addition. In 1,4-addition, the unsaturated bonds may be either of *cis* or of *trans* configuration. Polybutadienes containing a more or less random mixture of these polymer units can be prepared with alkali metal catalysts or with emulsion polymerization systems, but these have not achieved complete commercial significance as general-purpose rubbers in the United States.

In recent years, new catalysts have been developed that allow the structure of the polymer chain to be controlled. Polybutadienes containing an excess of 85% of either *cis*, *trans*, or vinyl unsaturation have been studied and, in the case of *cis* and *trans* polymers, produced commercially. It is also possible to prepare a number of other polymers with various combinations of these three component structures.

P

Of current importance are those types commercially available, which are (1) polymers of high *cis*-1,4 content (more than 85%) with low *trans* and vinyl content; (2) polymers of more than 80% *trans*, low *cis*, and low vinyl content; and (3) polymers of intermediate *cis* content (approximately 40% *cis*, 50% *trans*) with low vinyl content.

High-*cis* Polybutadiene

Outstanding properties of high-*cis* polybutadiene are high resilience and high resistance to abrasion. The high resilience is indicative of low hysteresis loss under dynamic conditions, that is, low heat rise in the polymer under rapid, repeated deformations. In this respect, *cis*-polybutadiene is similar to natural rubber. The combination of good hysteresis properties and resistance to abrasion makes this polymer attractive for use in tires, especially in heavy-duty tires where heat generation is a problem.

Another favorable factor, particularly for use in tire bodies, is that high-*cis* polybutadiene imparts good resistance to heat degradation under heavy loads in dynamic applications. Tensile strength in reinforced stock is lower than for natural rubber or styrene-butadiene rubber (SBR) but is adequate for many uses. Modulus depends on the degree of cross-linking, but *cis*-polybutadiene generally requires relatively low stress to reach a given elongation (at slow deformation). Hardness may be varied depending on the compound formulation and is similar to that of SBR and natural rubbers. Ozone resistance is typical of unsaturated polymers and is inferior to that of saturated rubbers. Oil resistance is comparable to that of SBR and natural rubber. Permeability to gases is higher than that of most other rubbers, which may be either an advantage or a disadvantage, depending on the application. Freezing point is quite low; *cis*-polybutadiene tread compounds do not become brittle until very low temperatures are reached, lower than -101°C .

Abrasion resistance of the high-*cis* polybutadiene varies with the type of service and in nearly all cases is superior to that of natural rubber or SBR. The advantage for these polybutadienes in relation to natural rubber and SBR increases as the severity of the service increases. From 30% to as high as 100% improvement in wear resistance has been reported through the substitution of these polybutadienes for natural rubber in tire treads.

Processing

Polybutadiene rubbers in general are more difficult to process in conventional equipment than natural rubber, particularly with regard to milling and extrusion operations. The processing problems have been overcome in many cases by treating the polymer, changing compounding formulations, or blending with other rubbers. Blends of natural rubber and a high-*cis* polybutadiene are particularly attractive. The presence of natural rubber alleviates the processing difficulties and improves tensile and tear properties of the polybutadiene, while the latter improves abrasion resistance and complements the already good hysteresis properties of natural rubber.

Processability can also be improved by the use of higher levels of reinforcing fillers and oils than normally employed. Consideration must also be given to changes in quality, but extension with 35–70 phr oil is possible with retention of properties suitable for tires and many rubber goods. Even in blends with natural rubber, where processing is not a problem, increases in carbon black and oil content have proved practical and often desirable.

Applications

For most uses, vulcanization is necessary to develop the desired strength and elastic qualities. The polymer chain is unsaturated and

can be readily vulcanized with sulfur (in conjunction with the usual activators) or with other cross-linking agents such as peroxides. With some exceptions, admixture of the rubber with a reinforcing pigment is required to obtain high strength. Antioxidants should be used for most applications. Lower than normal sulfur levels provide a better balance of properties in many instances, particularly with blends of high-*cis* polybutadiene and natural rubber.

In large tires, the use of blends of high-*cis* polybutadiene and natural rubber in treads improves both abrasion resistance and resistance to tread groove cracking compared to natural rubber alone. Substitution of high-*cis* polybutadiene for a portion of the natural rubber in the tire body has improved resistance to blowout or other heat failures (in some cases to a remarkable degree).

The high-*cis* polybutadienes are also used in increasing quantity in blends with SBR for the production of tires for passenger cars and small trucks. In this use, advantages include improved resistance to abrasion and cracking as well as adaptability to extension with large amounts of oil and carbon black.

As indicated, properties of high-*cis* polybutadiene are well suited for tire use, and this is expected to be the major application. Its use should be considered in other areas where high resilience, resistance to abrasion, or low-temperature resistance is required. Sponge stocks, footwear, gaskets and seals, and conveyor belts are possible applications. In shoe heels, high-*cis* polybutadiene may be used to provide good resilience and better abrasion resistance than realized with other commonly used rubbers. In shoe soles designed to be soft and resilient, high-*cis* polybutadiene has been used as a partial or total replacement for natural rubber to maintain high resilience, improve abrasion resistance, and provide better resistance to crack growth.

An important use for high-*cis* polybutadiene is in blends with other polymers to improve low-temperature properties. Replacement of 35% of an acrylonitrile (nitrile) rubber in a compound with *cis* polybutadiene can reduce the brittleness failure temperature from -40°C to -55°C . Similarly, it is possible to reduce the brittle point of neoprene compounds by some -6.7°C with the substitution of *cis* polybutadiene for one-fourth of the neoprene rubber. Such substitutions usually reduce resistance to swelling in hydrocarbons, but this effect can be lessened by compounding with oil-resistant resins or by using *cis* polybutadiene as a replacement for plasticizer in the compound rather than as a replacement for the polymer. In many cases, of course, oil resistance is not required, and *cis* polybutadiene may be blended with various polymers to give low-temperature properties approaching those of special arctic rubbers such as butadiene-styrene copolymers with low styrene content.

Partial substitution of *cis* polybutadiene for other rubbers used in light-colored or black-reinforced mechanical goods can provide a product that displays better slap. Also, resilience, abrasion resistance, and low-temperature properties are usually improved; tensile strength and tear strength may be reduced but shows less decline after aging.

High-*cis* polybutadienes have been used successfully as base components of caulking compounds and sealants. Another use is as a base polymer for graft polymerization of styrene to produce high-impact polystyrene.

Commercially available *cis* polybutadiene rubbers are supplied in talc form. The rubber contains a small amount of antioxidant to provide stability during storage.

High-*Trans* Polybutadiene

In contrast to the soft, rubbery nature of *cis* polybutadiene, polybutadiene of high *trans* content is a hard, horny material at room temperature. It is thermoplastic and thus can be molded without

addition of vulcanization agents. The softening point, hardness, and tensile strength increase with increasing *trans* content. A polymer of approximately 90% *trans* content, for example, displays a softening point near 93°C, Shore A hardness of about 98, and tensile strength of more than 6.8 MPa without addition of other ingredients.

High-*trans* polybutadiene can be readily vulcanized with sulfur or peroxides. It remains a hard, partially thermoplastic material when lightly vulcanized but can be made rubbery by increasing the curative level. Tensile strength is increased by the addition of reinforcing pigments (carbon black, silica, or clay). Compounded in such a manner, high-*trans* polybutadienes are characterized by high modulus, tensile strength, elongation, and hardness, by moderate resilience, and by excellent abrasion resistance.

In vulcanized stocks, properties such as hardness, resilience, and heat buildup can be modified.

Uses

Applications include those where balata has been used such as in golf ball covers and wire and cable coverings. Properties have also been demonstrated to be suitable for shoe soles (high hardness, good abrasion resistance), floor tile (high hardness, low compression set), gasket stocks, blown sponge compounds, and other molded or extruded items. High-*trans* polybutadiene requires processing temperatures above its softening point but is relatively easy to mix, mill, or extrude at these temperatures. Care should be taken to avoid scorch or preure when handling stocks containing curatives at elevated temperatures.

Polybutadiene of Intermediate *cis* Content

This type of product has a structure of approximately 40% *cis*, 50% *trans*, and 10% (or less) vinyl content.

The raw polymer is often somewhat waxlike in character. This polybutadiene displays high resilience, high dynamic modulus, and a low brittle point.

Processing difficulties in milling and extrusion operations may be encountered, and it is usually recommended that polybutadienes of intermediate *cis* content be used in blends with other rubbers. In tire treads, substitution of 40% *cis*-polybutadiene for a portion of the natural rubber or SBR 1500 improves resilience and abrasion resistance and gives some reduction in operating temperature. Other applications include products where similar changes in the aforementioned properties are desired or products where improvements in low-temperature properties are desired.

Liquid Polymers

Liquid polybutadienes can be prepared in most of the systems used to make solid rubbers. Such polymers may be cross-linked with chemicals or solidified with heat. One type of liquid polybutadiene has been manufactured on a small-scale utilizing sodium catalyst. Uses for this type of polymer include coatings, binders, adhesives, potting agents, casting and laminating resin, or vulcanizable plasticizer for rubber.

Polychromator

A *spectrometer* that has many (typically 20–50) detectors for simultaneously measuring light from many spectral lines. Polychromators are commonly used in atomic emission spectroscopy. See also *monochromator*.

Polycondensation

See *condensation polymerization*.

Polycrystalline

Pertaining to a solid comprised of many crystals or crystallites, intimately bonded together. May be homogeneous (one substance) or heterogeneous (two or more crystal types or compositions).

Polyester Film

Polyester film is a transparent, flexible film, ranging from 0.15 to 14 mils and thickness, used as a product component, in industrial processes, and for packaging. The most widely used type is produced from polyethylene terephthalate (i.e., *Mylar*). Polyester films based on other polymers or copolymers or manufactured by other methods are not identical, although they are similar in nature.

It is the strongest of all plastic films and strength is probably the outstanding property. However, it is useful as an engineering material because of its combination of desirable physical, chemical, electrical, and thermal properties. For example, strength combined with heat resistance and electrical properties makes it a good material for motor slot liners.

Polyester film was made by the condensation of terephthalic acid and ethylene glycol. The extremely thin film, 0.00063–0.0013 cm, used for capacitors and for insulation of motors and transformers, has a high dielectric strength, up to 236×10^6 V/m. It has a tensile strength of 137 MPa with the elongation of 70%. It is highly resistant to chemicals and has low water absorption. The material is thermoplastic, with a melting point at about 254°C. Polyester fibers are widely used in clothing fabrics. The textile fiber produced from dimethyl terephthalate is known as *Dacron*.

For magnetic sound-recording tape, polyester tape has the molecules oriented by stretching to give high strength. The 0.013 cm tape has a breaking strength of 3.4 kg/0.64 cm in width. Electronic tape may also have a magnetic-powder coating on the polyester. But where high temperatures may be encountered, as in spacecraft, the magnetic coating is applied to metal tapes.

Properties

Polyester film has excellent resistance to attack and penetration by solvents, greases, and oils and many of the commonly used electrical varnishes. At room temperature, permeability to such silences as ethanol, ethyl acetate, carbon tetrachloride, hexane, benzene, acetone, and acetic acid is very low. It is degraded by some strong alkali compounds and embrittles under severe hydrolysis conditions.

Moisture absorption is less than 0.8% after immersion for a week at 25°C. Water vapor permeability is similar to that of polyethylene film and permeability to gases is very low. The film is not subject to fungus attack and copper corrosion is negligible.

An outstanding feature of the film is the fact that good physical and mechanical properties are retained over a wide temperature range. Service temperature range is –60°C to 150°C. The effect of temperature is relatively small between –20°C and 80°C. No embrittlement occurs at temperatures as low as –60°C, and useful properties are retained up to 150°C–175°C. Tensile modulus drops off sharply at 80°C–90°C.

Melting point is 250°C–255°C, thermal coefficient of expansion is 15×10^{-6} in./in./°F; and shrinkage at 150°C is 2%–3%.

Fabrication and Forms

Polyester film can be printed, laminated, metallized, coated, embossed, and dyed. It can be split into extremely narrow tapes (0.038 mm and narrower), and light gauges can be wound into spiral tubing. Heavy gauges can be formed by stamping or vacuum (thermo-) forming.

P

Matte finishes can be applied, and adhesives for bonding the film to itself and practically any other material are available.

Because of its desirable thermal characteristics, polyester film is not inherently heat sealable. However, some coated forms of the film can be heat-sealed, and satisfactory seals can be obtained on the standard film by the use of a benzyl alcohol, heat, and pressure.

Polyethylene terephthalate film is available in several different types:

- A. General-purpose and electrical film for wide variety of uses
- C. Special electrical applications requiring high insulation resistance
- D. Highly transparent film, minimum surface defects
- K. Coated with a polymer for heat sealability and outstanding gas and moisture impermeability
- HS. Shrinks uniformly about 30% when heated to approximately 100°C (after shrinking, it has substantially the same characteristics as the standard film)
- T. A film with high tensile strength (available in some thin gauges) with superior strength characteristics in the machine direction, designed for use in tapes requiring high-strength properties
- W. For outdoor applications, resistant to degradation by ultra-violet light

Applications

The range of properties outlined previously has made polyester film functional in many totally different industrial applications and suggests its use in numerous other ways.

The largest current user of the film is the electrical and electronic market, which uses it as slot liners in motors and as the dielectric for capacitors, replacing other materials that are less effective, bulkier, and more expensive. It is found in hundreds of wire and cable types, sometimes used primarily as an insulating material, sometimes for its mechanical and physical contributions to wire and cable construction. Reduction of cost of materials and processing can improve cable performance result.

Magnetic recording tapes for both audio and instrumentation uses are based on polyester film. In audio application, they contribute toughness, durability, and long play, or for instrumentation tapes, the film ensures maximum reliability. The film has proved to be a highly successful new material for the textile industry since it can be used to produce metallic yarns that are nontarnishing and unusually strong. They can be run unsupported, knit, dyed at the boil, and either laundered or dry-cleaned. Yarns are made by laminating the film to both sides of aluminum foil or by laminating metallized and transparent film. The structure is then slit into the required yarn widths.

As a surfacing material, polyester film is used on both flexible and rigid substrates for both protective and decorative purposes. Metallized, laminated to vinyl, and embossed, the film becomes interior trim for automobiles, for example.

With a special coating, the film becomes a drafting material that is tougher and longer lasting than drafting cloth. It is used for map-making, templates, and other applications in which its dimensional stability becomes a significant factor.

Strength in thin sections makes the film advantageous for sheet protectors, cardholders, sheet reinforcers, and similar stationery products. Pressure-sensitive adhesives make the properties of the film available for uses ranging from decorative trim to movie splicing.

The weatherable form (type W) has a life of 4–7 years. It is principally used in greenhouses, where it cuts construction costs by as

much as two-thirds because a simple, inexpensive structure suffices and maintenance costs are at a minimum.

In the packaging field, polyester film serves in areas where other materials fail or have functional disadvantages. In window cartons, it lasts longer and does not break as other materials do; its toughness permits transparent packaging of heavy items, and, coated with polyethylene, it has made possible the “heat-in-the-bag” method of frozen-food preparation.

An optically clear form of polyester film in thicknesses of 4–7 mils is used as a base for the coating of light-sensitive emulsions in the manufacture of photographic film. The outstanding qualities of toughness and dimensional stability make this film especially well suited as a base for graphic arts films, motion picture film, engineering reproduction films, and microfilm. Other advantages include excellent storage and aging characteristics.

Polyester Plastics

The materials are commonly called polyester resins, but this simple name does not distinguish between at least two major classes of commercial materials. Also, the same name is used within the unsaturated class to designate both the cured and uncured state. These plastics may be defined by identifying the materials as “unsaturated polyester resins that, when cured, yield thermoset products as opposed to thermoplastic products.” The latter, as exemplified by *Dacron* and *Videne*, are saturated polyesters.

Composition

Unsaturated polyester resins of commerce are composed of two major components, a linear, unsaturated polyester and a polymerizable monomer. The former is a condensation type of polymer prepared by esterification of an unsaturated dibasic acid with a glycol. Actually, most polyesters are made from two or more dibasic acids.

The most commonly used unsaturated acids are maleic or fumaric with limited quantities of others used to provide special properties. The second acid does not contain reactive unsaturation. Phthalic anhydride is most commonly used, but adipic acid and, more recently, isophthalic acid are employed. The properties of the final product can be varied widely, from flexible to rigid, by changing the ratios and components in the polyester portion of the resin.

The polyesters vary from viscous liquids to hard, brittle solids but, with a few exceptions, are never sold in this form. Instead, the polyester is dissolved in the other major component, a polymerizable monomer. This is usually styrene; diallyl phthalate and vinyl toluene are used to a lesser extent. Other monomers are used for special applications.

Polyester resins may contain numerous minor components such as light stabilizers and accelerators, but must contain inhibitory components so that storage stability is achieved. Otherwise, polymerization will take place at room temperature.

The most widely used polyester resins are supplied with viscosities in the range of 300–5000 centipoise. They are clear liquids varying in color from nearly water-white to amber. They can be colored with certain common pigments, which are available ground in a vehicle for ease of dispersion. Inert, inorganic fillers such as clays, talcs, and calcium carbonates are often added, usually by the fabricator, to reduce shrinkage and lower costs. Resins with thixotropic properties are also available.

Curing

The liquid resins are cured by the use of peroxides with or without heat to form solid materials. During the cure, the monomer

copolymerizes with the double bonds of the unsaturated polyester. The resulting copolymer is thermoset and does not flow easily again under heat and pressure. Heat is involved during the cure. This must be considered when thick sections are made. Also, a volume shrinkage occurs and the density increases to 1.20–1.30. The amount of shrinkage varies between 5% and 10% depending on monomer content and degree of unsaturation in the polyester. The most popular catalyst is benzoyl peroxide but methylethyl ketone peroxide, cumene hydroperoxide, and others find application.

Reinforcement

The development of this field of commercial resins owes a great deal to the commercial production of two other products: The first was the production of low-cost styrene for the synthetic rubber program. Other cheap monomers will work but not nearly as well. Styrene and its homologues have relatively high boiling points and fast polymerization rates. Both properties are important in this field.

The second development was the commercial production of fibrous glass. Polyester resins are not widely used as cast materials nor are the physical properties of such castings particularly outstanding.

The unique property of polyesters is their ability to change from a liquid to a hard solid in a very short time under the influence of a catalyst and heat. This property was not available in any of the earlier plastic materials. Polyesters flow easily in a mold with little or no pressure so that expensive, high-pressure molds are not required. Alternatively, very large parts can be made because the total pressure required to form the material is low.

Glass fibers of fine diameter have high tensile strengths, good electrical resistance properties, and low specific gravity when compared to metals. When such fibers are used as reinforcement for polyester resins (like steel in concrete), the resulting product possesses greatly enhanced properties. Specific physical properties of the polyester resins may be increased by a factor varying from 2 to 10. Naturally, the increase in physical strengths obtained will depend upon both the amount of glass fibers used and their form. Strengths approaching those of metals on an equal weight basis are obtained with some constructions.

Fabrication Techniques

Hand Lay-Up

This method involves the use of either male or female molds. Products requiring the highest physical properties are made with glass cloth. The cloth may be precoated with resin, but usually, one ply is laid on or in the mold, coated with resin by brushing or spraying, and then a second ply of cloth laid on top of the first. The process is continued until the desired thickness is built up. Aircraft parts, such as radomes, usually require close tolerances on dimensions and resin-to-glass weight ratio. After the lay-up has been completed, pressure is applied either by covering the assembly with flexible, extensible blanket or drawing it down by vacuum, or the mold is so made that a rubber bag can be contained above the part. This is then blown up to apply pressure on the laminate. Thereafter, the cure is accomplished by heating in an oven, by infrared lamps, or by heating means built into the mold.

Corrugated Sheet Molding

Glass-reinforced polyester sheets are sold in large volume and are made by a relatively simple intermittent or continuous method. The process consists of placing a resin-impregnated mat between

cellophane sheets, rolling or squeezeegeeing out the air, placing the assembly between steel and aluminum molds of the desired corrugation, and curing the assembly in an oven.

Matched Die Molding

This method produces parts rapidly and generally of uniform quality. The molds used are somewhat similar to those employed in compression molding, usually of two-piece, mating construction. The process consists of two steps. A “preform” of glass fibers is prepared by collecting fibers on a screen, which has the shape of the finished article. Suction is used to hold the fibers on the screen; fibers are either blown at it or fall on it from a cutter. Commercial equipment is available for this operation. When the desired weight of glass fibers has been collected, a resinous binder is applied. The preform and screen are then baked to cure the binder, after which the preform is ready for use. The second step is the actual molding. The preform is placed in the mold, the catalyzed resin poured on the preform in correct amount, the mold closed, and the cure affected by heat. Design of the mold is very important, and some features are different from those in other molding fields.

Molding cycles vary from 2 to 5 min at a temperature from 110°C to 149°C. Trimming, sanding, and buffing are usually required at the flash line.

Premix Molding

This branch of the field provides parts for automotive and similar end uses. The parts are strictly functional and are usually pigmented black. The strength properties required are relatively low except that impact strength must be good. As the name infers, the unsaturated resin is first mixed with fillers, fibers, and catalyst to pursue a nontacky compound. The mixers used are of the heavy-duty Day or Baker Perkins type. The “premix” is usually extruded to provide a “rope” or strip of material easily handled at the press. The fibers used most extensively are cut sisal, but glass and asbestos are also used, and frequently all three are present in a compound. The fillers are clays, carbonates, and similar cheap inorganic materials. A typical premix will contain 38% catalyzed unsaturated resin, 12% total fiber, and 50% filler. However, rather wide variations in composition are practiced to obtain specific end-use properties.

The premix is molded at pressures of 103–350 MPa and at temperatures ranging from 121°C to 154°C. Cure cycles are short, usually from 30 to 90 s. Again, the fact that the resin starts as a liquid makes possible the molding of intricate parts because of ease of flow in the mold. Heater housings for autos are the largest use, but housings of many types and electrical parts are produced in volume. This process provides a cheap but very serviceable molded material.

Properties

The strengths obtainable in the finished product are of prime interest to the engineer. However, the numerous forms of reinforcement materials and the variations possible in the polyester constituent present a whole spectrum of obtainable properties. As an example, products are available that will resist heat for long periods of time at temperatures varying from 66°C to 177°C, but the higher the temperature, the more expensive the resin.

In general, the commercial resins have good electrical properties and are resistant to dilute chemicals. Alkali resistance is poor, as is resistance to strong acids. The strength-to-weight ratio of polyester parts and their impact resistance are outstanding physical properties.

Available Forms

Probably, over 95% of the unsaturated polyester resins sold are liquids in the uncured state. However, certain types are available in solid or paste form for special uses. The cured resins are available in laminate form as corrugated sheeting, which is sold widely for partitions, windows, patio roofs, etc. Rod stock may be purchased for fishing rods and electrical applications. Paper and glass cloth laminates are sold to fabricators. The boat end use is making the material more familiar to the general public. However, a large part of the industrial production is concerned with custom-molded parts. These are perhaps best classified by industries rather than specific products. The aircraft industry uses substantial quantities but automotive end uses are larger. The chemical industry is using increasing amounts in fume ducts and corrosion-resistant containers. The electrical industry uses the material in laminate and molded forms and as an encapsulation medium. Furniture applications are growing. The machinery industry uses moldings as housings and guards; a recent volume use is motorboat shrouds. There are few fields that have not found the material useful in some applications. See also *thermoplastic polymers*, *thermosetting polyesters*, and *unsaturated polyesters*.

Polyester Thermoplastic Resins

There are several types of melt-processable thermoplastics, including polybutylene terephthalate, polyethylene terephthalate, and aromatic copolyesters.

Polybutylene Terephthalate (PBT)

This plastic material is made by the transesterification of dimethyl terephthalate with butanediol through a catalyzed melt polycondensation. These molding and extrusion resins have good resistance to chemicals, low moisture absorption, relatively high continuous-use temperature, and good electrical properties (track resistance and dielectric strength). PBT resin is sensitive to alkalis, oxidizing acids, aromatics, and strong bases. Various additives, fillers, and fiber reinforcements are used with PBT resins, in particular flame retardants, mineral fillers, and glass fibers. PBT resins and compounds are used extensively in automotive, electrical–electronic, appliance, military, communications, and consumer product applications.

Polyethylene Terephthalate (PET)

This is a widely used thermoplastic packaging material. Beverage bottles and food trays for microwave and convection oven use are the most prominent applications. PET resins are made from ethylene glycol and either terephthalate acid or the dimethyl ester of terephthalic acid. Most uses for PET require the molecular structure of the material to be oriented. Orientation of PET significantly increases tensile strength and reduces gas permeability and water vapor transmission. For packaging uses, PET is processed by blow molding and sheet extrusion. Typical trade names are *Cleartuf*, *Traytuf*, *Tenite*, and *Kodapak*. Injection-molding grades of PET, with fillers and/or reinforcements, also are available for making industrial products.

Aromatic polyesters (liquid crystal polymers [LCP]) have high mechanical properties and heat resistance. Commercial grades are aromatic polyesters, which have a highly ordered or liquid crystalline structure in solution and molten states. A high degree of molecular orientation develops during processing and, hence, anisotropy in properties. Typically, these melt-processable resins can be molded or extruded to form products capable of being used at temperatures over 260°C. Tensile strengths up to 240.3 MPa and flexural moduli

up to 3586.3 MPa are reported for LCPs. Chemical resistance also was excellent. Trade names for LCPs include *Vectra* and *Xydur Granlar*. Applications are in chemical processing, electronic, medical, and automotive components.

Polyester Thermosetting Resins

These are a large group of synthetic resins produced by condensation of acids such as maleic, phthalic, or itaconic with an alcohol or glycol such as allyl alcohol or ethylene glycol to form an unsaturated polyester that, when polymerized, will give a cross-linked, 3D molecular structure, which in turn will copolymerize with an unsaturated hydrocarbon, such as styrene or cyclopentadiene, to form a copolymer of complex structure of several monomers linked and cross-linked. At least one of the acids or alcohols of the first reaction must be unsaturated. The polyesters made with saturated acids and saturated hydroxyl compounds are called alkyd resins, and these are largely limited to the production of protective coatings and are not copolymerized.

The resins undergo polymerization during cure without liberation of water and do not require high pressure for curing. Through the secondary stage of modification with hydrocarbons, a very wide range of characteristics can be obtained. The most important use of the polyesters is as laminating and molding materials, especially for glass-fiber-reinforced plastic products. The resins have high strength, good chemical resistance, high adhesion, and capacity to take bright colors. They are also used, without fillers, as casting resins, for filling and strengthening porous material such as ceramics and plaster of Paris articles and for sealing the pores in metal castings. Some of the resins have great toughness and are used to produce textile fibers and thin plastic sheet and film. Others resins are used with fillers to produce molding powders that cure at low-pressure of 3–6 MPa with fast operating cycles.

Polyester Laminates

These are usually made with a high proportion of glass-fiber mat or glass fabric, and high-strength reinforced moldings may also contain a high proportion of filler. A resin slurry may contain as high as 70% calcium carbonate or calcium sulfate, with only about 11% of glass fiber added, giving an impact strength of 165 MPa in the cured material. Bars and structural shapes of glass-fiber-reinforced polyester resins of high tensile and flexural strengths are made by having the glass fibers parallel in the direction of the extrusion. Rods and tubes are made by having the glass-fiber rovings carded under tension and then passing through an impregnating tank, an extruding die, and a heat-curing die. The rods contain 65% glass fiber and 35% resin. They have a flexural strength of 441 MPa and a Rockwell M hardness of 65.

Physical properties of polyester moldings vary with the type of raw materials used and the type of reinforcing agents. A standard glass-fiber-filled molding may have a specific gravity from 1.7 to 2.0, a tensile strength of 27–68 MPa with the elongation of 16%–20%, a flexural strength to 206 MPa, a dielectric strength to about 16×10^6 V/m, and a heat distortion temperature of 177°C–204°C. The moldings have good acid and alkali resistance. But, because an almost unlimited number of fatty-type acids are available from natural fatty oils or by synthesis from petroleum and the possibilities of variation by combination with alcohols, glycols, and other materials are also unlimited, the polyester forms an ever-expanding group of plastics.

Some of the polyester-type resins have rubberlike properties, with higher tensile strengths than the rubbers and superior resistance to oxidation. These resins have higher wear resistance and chemical resistance than GRS (Government Rubber Styrene), a copolymer of

butadiene and styrene rubber. They are made by reacting adipic acid with ethylene glycol and propylene glycol and then adding diisocyanate to control the solidifying action. They can be processed like rubber, but solidified more rapidly.

Polyetheretherketones (PEEKs)

The latest developments in PEEK resin formulations let manufacturers take advantage of its wear and strength qualities for pump applications.

Uses

Pumps with mating components made of cast iron, stainless steel, and bronze have long been a source of problems for manufacturers and end users. The abrasive quality of metals leads to significant wear in pump parts, which frequently results in failures from galling and seizing. As anyone working in a manufacturing environment knows, one's worst nightmare can come true when a pump runs dry or a bearing fails or shutting down an entire assembly line or plant operation. And the costs are hardly trivial for repairing all of the pump components destroyed or carrying out periodic maintenance on the equipment to handle such a nightmare.

Engineers are starting to replace metals with advanced plastics for pump components such as bushings, line shaft bearings, and case and impeller wear rings. The resins they use are based on PEEK chemistry and were initially developed for aerospace and defense applications. Using these engineered resins, pump manufacturers improve performance, boost output, and cut costs by taking advantage of better wear and friction qualities, mechanical strength, and the ability to resist chemicals.

The chemical makeup of PEEK resins helps ease engineers' concerns about galling and seizing and are safer to work with. Taking advantage of these qualities, along with an understanding of some basic design guidelines, opens new doors in pump performance and reliability.

Types, Fabrication, and Properties

Engineers often choose PEEK resin because of its overall balance of qualities, including hydrolysis resistance, dimensional stability, wear resistance, temperature stability, strength, and chemical resistance. However, switching from metal to plastic in pump parts requires engineers to change their mind-sets.

PEEK can be injection molded, compression molded, or extruded into stock shapes, which are typically machined to final-part dimensions. Most pump components can be injection molded as long as they do not require tight tolerances. The strict tolerances required for bushings and wear rings require parts to be machined from molded tube stock.

Although manufacturers may be used to machining metals, speeds and feeds are much different for plastics and the process generally calls for high-end carbide and diamond tooling. Machining operations vary depending on which fillers and reinforcements are used in each resin grade.

Even though plastics can be machined more quickly than metals, it is not as easy to hold tolerances because plastics tend to spring when parted off. Tolerances in the range of ± 0.05 mm can be held on parts with diameters up to 254 mm.

The most common blends of PEEK resin used in pump applications are carbon filled and carbon-fiber reinforced. Carbon-filled PEEK compounds can be molded in solids or tubes up to 101.6 cm in diameter. Carbon-fiber-reinforced resins, in contrast, are robotically

wound and formed around a mandrel. This limits fiber-reinforced resins to hollow shapes no smaller than 9.5 mm in diameter. Splitting hollow shapes is not recommended because the strength of the composite relies on the carbon fibers being molded and kept in tension.

Another difference between carbon-filled and carbon-fiber-reinforced PEEK resins is how they react to temperature changes. Carbon-filled compounds have a radial thermal expansion rate of 16×10^{-6} in./in./°F, while that of fiber-reinforced resins is less than 3×10^{-6} in./in./°F. These two values fall on either side of the thermal expansion rate of carbon steel, which is 6×10^{-6} in./in./°F, making the choice between the two resins critical when combining PEEK resins with metal pump housings and components.

Carbon-filled resins are recommended for press-in applications such as bushings and case wear rings. As temperatures rise, PEEK components will become tighter because they are expanding at a faster rate than the steels surrounding the bushings or rings. In contrast, carbon-fiber-reinforced resins work better for press-on applications such as impeller wear rings. The inside diameter of the wear ring fits on the impeller skirt, which has a slightly larger outside diameter than the ring inside diameter. As operating temperatures rise, the steel impeller skirt expands more quickly than the PEEK wear rings, creating a tighter fit.

In summary, when compared to carbon-fiber-reinforced resin, carbon-filled PEEK is less expensive and easier to machine and can be split without compromising physical properties. However, fiber-reinforced resins have the advantage when it comes to higher operating temperatures. Reinforced resins are also stronger than carbon-filled blends. Fiber-reinforced PEEK is a true metal replacement because it combines the physical properties of steel with the processing ease and flexibility associated with thermoplastics.

Applications

One area where metal-to-plastic conversions are reaping benefits is in the petroleum industry where multistage horizontal pumps often experience high vibration levels that frequently cause seals to fail. Vibrations wear down bronze bushings and case wear rings, which, in turn, reduce overall pump efficiency and increase maintenance costs.

Replacing bronze and steel wear rings with carbon-filled or carbon-reinforced PEEK components, allows manufacturers to increase pump efficiency by achieving tighter clearances. PEEK resins also reduce vibrations caused by fluid flow across wear rings and excess rotor runout.

The ductility of plastic pump components helps them outperform metal versions when it comes to reducing vibration, as well as resisting impact. For example, a petroleum refinery that once considered vibrations of 6.67 mm/s acceptable for two multistage pipeline diesel-fuel feed pumps was able to reduce vibration by more than 80% using carbon-filled PEEK case wear rings and bushings.

An added benefit when designing pump components from plastic is safety, particularly for industries working with flammable fluids. Plastics eliminate the risk of sparks when pumps run dry because of momentary suction losses during system upsets, which is a concern with metal-on-metal contact in conventional designs.

Another area is boiler-feed water pumps. Galling and even seizure are common concerns when using pumps with steel components and wear parts. This is especially true in water pumps where, because of the corrosion resistance of the material, stainless steels are used for pump parts as well as wear components. Although they protect pumps from corrosion, stainless steels gall more easily than other metals.

Engineers often design boiler-feed water pumps with tight diametrical running clearances to maximize discharge pressures. However, the tight clearances on stainless steel wear rings and

P

bushing severely damage pumps storing brief periods of cavitation. Cavitation takes place when suction pressures drop below the net positive suction head required by a pump. Momentary cavitations are common in pumps running close to the vapor pressure of a fluid, which is often the case in boiler-feed water pumps.

Wear, or hard rubs, resulting from cavitation often show up initially in the first-stage wear rings and the center-stage bushings. As a result, rotors deflect more, which causes pumps to seize.

Impeller wear rings and sleeves made of fiber-reinforced PEEK eliminate galling because the material can run for short periods without lubrication. As a result, PEEK wear parts and mating steel components remain undamaged during momentary system upsets. See also *polyaryletherketone*.

Polyetherimides (PEIs)

PEI is an amorphous engineering thermoplastic characterized by high heat resistance, high strength and modulus, excellent electrical properties that remain stable over a wide range of temperatures and frequencies, and excellent processability. Unmodified PEI resin is transparent and has inherent flame resistance and low-smoke evolution. The resin is produced as *Utem*.

Polyetherimide resin is available in an unreinforced grade for general-purpose injection molding, blow molding, foam molding, and extrusion, in four glass-fiber-reinforced grades (10%, 20%, 30%, and 40% glass), in bearing grades, and in several high-temperature grades. The unreinforced grade is available as a transparent resin and in standard and custom colors.

The resin can be processed on conventional thermoplastic molding equipment. Melting temperatures of 349°C–427°C are typical for injection-molding applications. Molding temperatures of 66°C–177°C are required.

Polyetherimide is extruded to produce profiles, coated wire, sheet, and film. Film thicknesses as low as 0.25 mil are obtained by solvent-casting techniques. Molded and extruded parts can be machined using either conventional or laser techniques and can be bonded together or to dissimilar materials using ultrasonic, adhesive, or solvent methods.

Properties

The Underwriters Laboratories' continuous-use listing of PEI is 170°C, glass transition temperature is 215°C, and heat-deflection temperature is 200°C at 1.78 MPa, contributing to its high strength and modulus retention for service under load at elevated temperatures.

A key feature of polyetherimide is maintenance of properties at elevated temperatures. For example, at 179°C, tensile strength and flexural modulus are 48 and 2040 MPa. Moduli and strengths of the glass-reinforced grades are still higher. For example, flexural modulus is 8840 MPa with 30% glass reinforcement, and more than 80% of this is retained at 179°C.

Polyetherimide has good creep resistance as indicated by its apparent modulus of 2403 MPa after 1000 h at 82°C under an initial applied load of 34.3 MPa.

The resin resists a broad range of chemicals under varied conditions of stress and temperatures. Compatibility has been demonstrated with aliphatic hydrocarbons and alcohols including gasoline and gasohol, mineral-salt solutions, dilute bases, and fully halogenated hydrocarbons. Resistance to mineral acids is outstanding. The polymer is attacked by partially halogenated solvents such as methylene chloride and trichloroethane and by strong bases.

Resistance to ultraviolet radiation is good; change in tensile strength after 1000 h of xenon arc exposure is negligible. Resistance

to gamma radiation is also good; strength loss is less than 6% after 500 Mrad exposure to cobalt-60 at the rate of one Mrad/h.

Hydrolytic stability tests show that more than 85% of tensile strength is retained after 10,000 hr of boiling water immersion. The material is also suitable for applications requiring short-term or repeated steam exposure.

Polyether Resins

These are thermoplastic or thermosetting materials that contain ether–oxygen linkages, $-C-O-C-$, in the polymer chain. Depending upon the nature of the reactants and reaction conditions, a large number of polyethers with a wide range of properties may be prepared.

The main groups of polyethers in use are epoxy resins, prepared by the polymerization and cross-linking of aromatic diepoxy compounds; phenoxy resins, high-molecular-weight epoxy resins; polyethylene oxide and polypropylene oxide (PPO) resins; polyoxymethylene, a high polymer of formaldehyde; and polyphenylene oxides, polymers of xylenols.

Epoxy Resins

The epoxy resins forms an important and versatile class of cross-linked polyethers characterized by excellent chemical resistance, adhesion to glass and metals, electrical insulating properties, and ease and precision of fabrication.

The type of curing agent employed has a marked effect on the optimum temperature of curing and has some influence on the final physical properties of the product. By judicious selection of the curing system, the curing operation can be carried out at almost any temperature from 0°C to 200°C.

Various fillers such as calcium carbonate, metal fibers and powders, and glass fibers are commonly used in epoxy formulations to improve such properties as the strength and resistance to abrasion and high temperatures.

Because of their good adhesion to substrates and good physical properties, epoxies are commonly used in protective coatings. Because of the small density change on curing and because of their excellent electrical properties, the epoxy resins are used as potting or encapsulating compositions for the protection of delicate electronic assemblies from the thermal and mechanical shock of rocket flight. Because of their dimensional stability and toughness, the epoxies are used extensively as dies for stamping metal forms, such as automobile gasoline tanks, from metal sheeting. Foams are also made.

By combining epoxies, especially the higher-performance types based on polyfunctional monomers, with fibers such as glass or carbon, exceedingly high moduli and strengths may be obtained. Thus, a typical carbon-fiber-reinforced epoxy may have a tensile modulus and strength of 500 and 2 GPa, respectively. Such composites are of importance in aerospace applications where high ratios of a property to density are desired, as well as in such domestic applications of sports equipment.

The adhesive properties of the resins for metals and other substrates and their relatively high resistance to heat and to chemicals have made the epoxy resins useful for protective coatings and for metal-to-metal bonding.

Polyolefin Oxide Resins

Polyethylene oxide and PPO are thermoplastic products whose properties are greatly influenced by molecular weight. Oxides, such as tetrahydrofuran, can also be polymerized to give polyethers.

Low- to moderate-molecular-weight polyethylene oxides vary in form from oils to waxlike solids. They have relatively nonvolatile, are

soluble in a variety of solvents, and have found many uses as thickening agents, plasticizers, lubricants for textile fibers, and components of various sizing, coating, and cosmetic preparations. The PPOs of similar molecular weight have somewhat similar properties, but tend to be more oil-soluble (hydrophobic) and less water soluble (hydrophilic).

Phenoxy Resins

Phenoxy resins differ from the structurally similar epoxy resins based on the reaction of epichlorohydrin with bisphenol A maybe by possessing a much higher molecular weight, about 25,000. The polymers are transparent, strong, ductile, and resistance to creep and, in general, resemble polycarbonates in their behavior. Cross-linking may be affected by the use of curing agents that can react with the OH groups. Molding and extrusion may be used for fabrication. The major application is as a component in protective coatings, especially in metal primers.

Polyphenylene Oxide (PPO) Resins

PPO is the basis for an engineering plastic characterized by chemical, thermal, and dimensional stability. The PPO resin is normally blended with another compatible but cheaper resin such as high-impact polystyrene. The blends are cheaper and more processable than PPO and still retain many of the advantages of PPO by itself.

PPO is outstanding in its resistance to water and at its maximum usable temperature range (about 170°C–300°C). In spite of the high softening point, the resins, including glass-reinforced compositions, can be molded and extruded in conventional equipment. Uses include medical instruments, pump parts, and insulation. Structurally modified resins are also of interest and the general family of resins may be expected to replace other materials in many applications.

Commercial products can be processed by injection or compression molding as well as by slurry or electrostatic coating; reinforcement with glass fibers is also commonly practiced. The combination of properties is useful in such applications as electronic pumps and automotive components and coatings, especially where environmental stability is required.

Polyoxymethylene (POM)

POM, or polyacetal, resins are polymers of formaldehyde. With high molecular weights and high degrees of crystallinity, they are strong and tough and are established in the general class of engineering thermoplastics.

Although somewhat similar to polyethylene in general molecular structure, polyacetal molecules pack more closely and attract each other to a much greater extent, so that the polymer is harder and has higher melting point than polyethylene. Polyacetals are typically strong and tough and resistant to fatigue, creep, organic chemicals (but not strong acids or bases) and have low coefficients of friction. Electrical properties are also good. Improved properties for particular application may be attained by reinforcement with fibers of glass or polytetrafluoroethylene.

The combination of properties has led to many uses such as plumbing fittings, pump and valve components, bearings and gears, computer hardware, automobile body parts, and appliance housings. Other aldehydes may be polymerized in a similar way.

Polyethersulfone

A high-temperature engineering thermoplastic consisting of repeating phenyl groups linked by thermally stable ether and sulfone groups. The material has good transparency and flame resistance and is one of the lowest smoke-emitting materials available.

Both polymer and reinforced grades are available in granular form for extrusion or injection molding.

Polyethylene

Polyethylene thermoplastic resins include low-density polyethylenes (LDPE); linear low-density polyethylenes (LLDPE); high-density polyethylenes (HDPE); and ethylene copolymers, such as ethylene–vinyl acetate (EVA) and ethylene–ethyl acrylate (EEA); and ultra-high-molecular-weight polyethylenes (UHMWPE). In general, the advantages gained with polyethylenes are lightweight, outstanding chemical resistance, good toughness, excellent dielectric properties, and relatively low cost compared to other plastics. The basic properties of polyethylenes can be modified with a broad range of fillers, reinforcements, and chemical modifiers, such as thermal stabilizers, colorants, flame retardants, and blowing agents. Further, polyethylenes are considered to be very easy to process by such means as injection molding, sheet extrusion, film extrusion, extrusion coating, wire and cable extrusion coating, blow molding, rotational molding, fiber extrusion, pipe and tubing extrusion, and powder coating. Major application areas for polyethylenes are packaging, industrial containers, automotive, materials handling, consumer products, medical products, wire and cable insulation, furniture, housewares, toys, and novelties.

Polyethylene is a water-repellent, white, tough, leathery, thermoplastic resin very similar in appearance to paraffin wax. Properties vary from a viscous liquid at low molecular weights to a hard wax-like substance and high molecular weights. It is used as a coating for glass bottles and fiberglass fabrics (special treatments for glass are required to obtain good adhesion between polyethylene and glass) and is also used as an injection-molding material for ceramics.

The basic building blocks for polyethylenes are hydrogen and carbon atoms. These atoms are combined to form the ethylene monomer, C_2H_4 , that is, two carbon atoms and four hydrogen atoms. In the polymerization process, the double bond connecting the carbon atoms is broken. Under the right conditions, these bonds reform with other ethylene molecules to form long molecular chains. Ethylene copolymers, EVA, and EEA, are made by the polymerization of ethylene units with randomly distributed comonomer groups, such as vinyl acetate and ethyl acrylate.

Properties

Three basic molecular properties affect most polyethylene properties: crystallinity (density), average molecular weight, and molecular weight distribution.

Molecular chains in polyethylenes in crystalline areas are arranged somewhat parallel to each other. In amorphous areas, they are randomly arranged. High-density polyethylene resins have molecular chains with comparatively few side chain branches. Therefore, the chains are packed more closely together. The result is crystallinity up to 95%. LDPE resins have crystallinity from 60% to 75%. LLDPE resins have crystallinity from 60% to 85%. For polyethylenes, the higher the degree of crystallinity, the higher the resin density. Higher density, in turn, influences numerous properties. With increasing density, heat-softening point, resistance to gas and moisture vapor permeation, and stiffness increase. However, increased density results in a reduction of stress cracking resistance and low-temperature toughness. LLDPE resins range from 0.910 to 0.930 g/cm³; LDPE resins range from 0.9102 to 0.930 g/cm³ and HDPE from 0.941 to 0.965 g/cm³.

High-molecular-weight LDPE resins are used to extrude high clarity, tough film used in shrink packaging and for making heavy-duty bags. High-molecular-weight HDPE resins (ave. MW 200,000–500,000) have excellent environmental stress cracking resistance, toughness, high moisture barrier properties, and high strength

P

and stiffness. The high-molecular-weight HDPE resins are used in film, pressure pipe, large blow moldings, and sheet for thermoforming. UHMWPEs generally are considered to be those resins with molecular weights greater than two million (materials with MW up to six million are available). These resins have excellent abrasion resistance, stress cracking resistance, and toughness. They are, however, much more difficult to process than standard polyethylenes and require special forming techniques. UHMWPE resins are used in applications requiring high wear resistance, chemical resistance, and low coefficient of friction.

Polyethylene rubbers are rubberlike materials made by cross-linking with chlorine and sulfur, or they are ethylene copolymers. Chlorosulfonated polyethylene is white spongy material, in which chlorine atoms and sulfonyl chloride groups are spaced along the molecule. It is used to blend with rubber to add stiffness, abrasion resistance, and resistance to ozone and also for wire covering. Ethylene-propylene rubber, produced by various companies, is a chemically resistant rubber of high tear strength. The ethylene butadiene resin can be vulcanized with sulfur to give high hardness and wide temperature range. For greater elongation, a terpolymer with butene can be made.

Polyethylene of low molecular weight is used for extending and modifying waxes and also in coating compounds especially to add toughness, gloss, and heat-sealing properties. Such materials are called *polyethylene wax*, but they are not chemical waxes. They can be made emulsifiable by oxidation, and they can be given additional properties by copolymerization with other plastics. The polymethylene waxes are microcrystalline and have sharper melting points than the ethylene waxes. They are more costly, but have a high luster and durability. Polybutylene plastics are rubberlike polyolefins with superior resistance to creep and stress cracking. Films of this resin have high tear resistance, toughness, and flexibility and are used widely for industrial refuse bags. Chemical and electrical properties are similar to those of polyethylene and polypropylene plastics. Polymethyl pentene is a moderately crystalline polyolefin plastic resin that is transparent even in thick sections. Almost optically clear, it has a light transmission value of 90%. Parts molded of this plastic are hard and shiny with good impact strength down to -29°C . Its specific gravity (0.83) is the lowest of any commercial solid plastic. A major use is for molded food containers for quick frozen foods that are later heated by the consumer.

LDPE

LDPE, the first of the polyethylenes to be developed, has good toughness, flexibility, low-temperature impact resistance, clarity in film form, and relatively low heat resistance. Like the higher-density grades, LDPE has good resistance to chemical attack. At room temperature, it is insoluble in most organic solvents but is attacked by strong oxidizing acids. At higher temperatures, it becomes increasingly more susceptible to attack by aromatic, chlorinated, and aliphatic hydrocarbons.

Polyethylene is susceptible to environmental and some chemical stress cracking. Wetting agents such as detergents accelerate stress cracking. Some copolymers of LDPE are available with improved stress-crack resistance.

About half of LDPE production goes into packaging applications such as industrial bags, shrink bundling, soft goods, and produce and garment bags. Other applications include blow-molded containers and toys, hot-melt adhesives, injection-molded housewares, paperboard coatings, and wire insulation. LDPE resins are rotationally molded into large agricultural tanks, chemical shipping containers, tote boxes, and battery jars.

One of the fastest-growing plastics is linear LLDPE, used mainly in film applications but also suitable for injection, rotational, and blow molding. Properties of LLDPE are different from those of conventional LDPE and HDPE in that impact, tear, and heat-seal strengths and environmental stress-crack resistance of LLDPE are significantly higher. Major uses at present are grocery bags, industrial trash bags, liners, and heavy-duty shipping bags for such products as plastic resin pellets.

HDPE

Rigidity and tensile strength of the HDPE resins are considerably higher than those properties in the low- and medium-density materials. Impact strength is slightly lower, as is to be expected in a stiffer material, but values are high, especially at low temperatures, compared with those of many other thermoplastics.

HDPE resins are available with broad, intermediate, and narrow molecular weight distribution, which provides a selection to meet specific performance requirements. As with the other polyethylene grades, very-high-molecular-weight copolymers of HDPE resins are available with improved resistance to stress cracking.

Applications of HDPE range from film products to large, blow-molded industrial containers. The largest market area is in blow-molded containers for packaging milk, fruit juices, water, detergents, and household and industrial liquid products. Other major uses include high-quality, injection-molded housewares, industrial pails, food containers, and tote boxes; extruded water and gas-distribution pipe, and wire insulation; and structural-foam housings.

HDPE resins are also used to rotationally mold large, complex-shaped products such as fuel tanks, trash containers, dump carts, pallets, agricultural tanks, highway barriers, and water and waste tanks for recreational vehicles.

A special category of HDPE known as high-molecular-weight HDPE (HMW-HDPE) offers outstanding toughness and durability, particularly at low temperatures. These characteristics result from a unique combination of high average molecular weight (250,000–500,000) and a bimodal molecular weight distribution.

In blow-molding applications, HMW-HDPE allows drum manufacturers to meet Department of Transportation and Occupational Health and Safety Administration specifications. In pipe production, HMW-HDPE meets PE-3408, currently the highest strength rating for polyethylene pipe. Extruded sheet applications include pond liners, truck bed liners, and outdoor leisure products. The primary market, however, for HMW-HDPE is in film applications, where its toughness allows down-gauging in merchandise bags and trash bags. The material is also suited for use in T-shirt-type grocery sacks requiring high handle strength.

UHMWPE

UHMWPE was originally defined as a polyethylene whose average molecular weight, as measured by the solution-viscosity method, is greater than 2,000,000. (Molecular weight of HDPE ranges from 100,000 to 500,000.) Over the years, producers and processors of UHMWPE materials have tried to reach agreement on just how high is "ultrahigh." The values proposed in the past have ranged from as low as 1,000,000 to over 3,500,000. Also in dispute was the question of the relationship between molecular weight and properties of UHMWPE in finished parts.

Several years ago, a value of 3,100,000 was agreed upon for the molecular weight as the dividing line, above which the UHMW description should apply. Resin properties increase with increasing molecular weight and start to level off at the 3,100,000 value.

Also, processability is more difficult above that dividing line, and material cost rises more rapidly.

As with most high-performance polymers, processing of UHMWPE is not easy. Because of its high melt viscosity (it does not register a melt-flow index), conventional molding and extrusion processes would break the long molecular chains that give the material its excellent properties. Methods used currently are compression molding, ram extrusion, and warm forging of extruded slugs. Developmental work has been done on injection molding of UHMWPE resins, but the process forces the polymer to behave in a manner that is not conducive to maintaining its molecular structure. Compression-molded sheets as large as 1.43×4 m are available.

UHMWPE has outstanding abrasion resistance and a low coefficient of friction. Impact strength is high, and chemical resistance is excellent. The material does not break in impact strength tests using standard notched specimens; double-notched specimens break at 20 ft lb/in. Crystalline melting point of the material is 130°C. Recommended maximum service temperature is about 93°C, however, because of a high coefficient of thermal expansion.

Applications of UHMWPE include conveyor wear strips and guide rails, paper-machine suction-box covers, chute linings, and snowmobile-track sprockets, bearings, parts for textile looms, pipe for distribution of slurry materials, and other components requiring abrasion resistance, impact strength, and a low-friction coefficient. These plastics have outperformed other materials, including metals, in these applications.

Polyethylene Glycol

Polyethylene glycols or water-soluble, nonvolatile liquids and solids. Polyethylene glycols dissolve in water to form transparent solutions and are also soluble in many organic solvents. They do not hydrolyze or deteriorate.

Characteristics

The intermediate members of the series with average molecular weights of 200–20,000 are produced as residue products by the sodium or potassium hydroxide-catalyzed batch polymerization of ethylene oxide onto water or monomer diethylene glycol. These polymers are formed by stepwise anionic addition polymerization and, therefore, possess a distribution of molecular weights. Examples of commercial uses for products in this range are in ceramic, metal forming, and rubber-processing operations; as drug suppository bases and in cosmetic creams, lotions, and deodorants; as lubricants; as disbursements for casein, gelatins, and inks; and as antistatic agents. These polyethylene glycols generally have low human toxicity.

The highest members of the series have molecular weights from 100,000 to 10,000,000. They are produced by special anionic polymerization catalysts that incorporate metal such as aluminum, calcium, zinc, and iron and coordinated ligands such as amides, nitriles, or ethers. These members of the polyethylene glycol series are of interest because of their ability at very low concentrations to reduce friction of flowing water.

Applications

Polyethylene glycol has a range of properties making it suitable for medical and biotechnical applications. These polymers of ethylene oxide are frequently described as amphiphilic, meaning that they are soluble both in water and in most organic solvents. The medical and biotechnical applications derived from this amphiphilicity, from

a lack of toxicity and immunogenicity, and from a tendency to avoid other polymers and particles also present in aqueous solution.

Attaching polyethylene glycol to another molecule provides the latter with enhanced solubility in solvents in which polyethylene glycol is soluble, and thus polyethylene glycol is attached to drugs to enhance water and blood solubility. Similarly, polyethylene glycol is attached to insoluble enzymes to impart solubility in organic solvents. These polyethylene glycol enzymes are used as catalysts for industrial reactions in organic solvents.

The tendency to avoid other polymers results in formation of two immiscible aqueous layers when a solution of a polyethylene glycol is mixed with certain other polymer solutions. These aqueous two-phase systems are used to purify biological materials such as proteins, and nucleic acids, and cells by partitioning of desired and undesired materials between the two phases.

The tendency of polyethylene glycols to avoid interaction with cellular and molecular components of the immune system results in the material being nonimmunogenic.

Ceramic applications are varied and interesting. For example, they may be used to bind glass tubes into bundles prior to cutting into lengths. They also have been used as components of ceramic slips and glazes for the manufacture of porcelain signs and other vitreous coatings.

As binders for colors, excellent adhesion is obtained when the coatings are sprayed on the ceramic surface. A crayon for applying identification marks or decorations to ceramic particles, prior to firing, may be made from pigmented polyethylene glycol. As an extrusion binder, it aids in slurring the clay, promotes die life, and gives good binding properties. The automatic extrusion of tile, pipe, and electrical insulators has been improved through its use. Polyethylene glycol is an effective additive for the electrophoretic coating of certain components for vacuum tubes.

Polyethylene Plastics

Thermoplastic materials composed of ethylene. They are normally translucent, tough, waxy solids that are unaffected by water and by a large range of chemicals. In common usage, these plastics have no less than 85% ethylene and no less than 95% total olefins. See also *high-density polyethylenes* and *ultrahigh-molecular-weight polyethylene*.

Polyethylene Terephthalate

A saturated thermoplastic polyester resins made by condensing ethylene glycol and terephthalic acid and used for fibers, films, and injection-molded parts. It is extremely hard, wear resistant, eventually stable, and resistant to chemicals, and it has good dielectric properties. Also known as polyethylene glycol terephthalate.

Polyfluorolefin Resins

These resins are distinguished by their resistance to heat and chemicals and by the ability to crystallize to a high degree. Several name products are based on tetrafluoroethylene (TFE), hexafluoropropylene (HFP), and monochlorotrifluoroethylene.

Copolymers of TFE and HFP with each other and of TFE and HEP with ethylene are available commercially.

Polytetrafluoroethylene (PTFE)

The polymer is insoluble and resistant to heat (up to 275°C) and chemical attack and, in addition, has a lowest coefficient of friction

P

of any solid. Because of its resistance to heat, the fabrication of PTFE requires modification of conventional methods. After molding the powdered polymer using a cold-press, the moldings are sintered at 316°C–400°C by procedures similar to those used in powder metallurgy. The sintered product can be machined or punched. Extrusion is possible if the powder is compounded with a lubricating material. Aqueous suspensions of the polymer can also be used for coating various articles. However, special surface treatments are required to ensure adhesion because PTFE does not adhere well to anything.

PTFE resin is useful for applications under extreme conditions of heat and chemical activity. PTFE bearings, valves seats, packings, gaskets, coatings, and tubing can withstand relatively severe conditions. Fillers such as carbon, inorganic fibers, and metal powder may be incorporated to modify the mechanical and thermal properties.

Because of its excellent electrical properties, PTFE is useful when a dielectric material is required for service at a high temperature. The nonadhesive quality is often turned to advantage in the use of PTFE to coat articles such as rolls and cookware to which materials might otherwise adhere.

Polymonochlorotrifluoroethylene

The properties of polymonochlorotrifluoroethylene (CTFE resin) are generally similar to those for polymonochlorotrifluoroethylene; however, the presence of the chlorine atoms in the former causes the polymer to be a little less resistant to heat and to chemicals. The polymonochlorotrifluoroethylene can be shaped by use of conventional molding and extrusion equipment, and it is obtained in a transparent, noncrystalline condition by quenching. Dispersions of the polymer in organic media may be used for coating.

The applications of polymonochlorotrifluoroethylene are in general similar to those for polytetrafluoroethylene. Because of its stability and inertness, the polymer is useful in the manufacture of gaskets, linings, and valve seats that must withstand hot and corrosive conditions. It is also used as a dielectric material, as a vapor and liquid barrier, and for microporous filters.

Copolymers

Copolymers of TFE and HFP propylene (fluorinated ethylene propylene [FEP] resins) and copolymers of TFE with ethylene are often used in cases where ease of fabrication is desirable. The copolymers can be processed by conventional thermoplastic techniques, and except for some diminution in the level of some properties, properties generally resemble those of the TFE homopolymer.

Copolymers of ethylene with CTFE can also be processed by conventional methods and have better mechanical properties than TFE, FEP, and PFA resins.

Polyvinylidene Fluoride

The properties are generally similar to those of the other fluorinated resins: relative inertness, low dielectric constant, and thermal stability (up to about 150°C). The resins (PVF₂ resins) are, however, stronger and less susceptible to creep and abrasion than TFE and CTFE resins.

Applications of polyvinylidene fluoride are mainly as electrical insulation, in piping and process equipment, and as a protective coating in the form of a liquid dispersion.

Fluorinated Elastomers

Several types of fluorinated, noncrystallizing elastomers were developed to meet needs (usually military) for rubbers that possess

good low-temperature behavior with a high degree of resistance to oils and to heat, radiation, and weathering.

Copolymers of hexafluoropropylene with vinylidene fluoride make up an important class with such applications as gaskets and seals. Copolymers of nitrosomethane with tetrafluoroethylene ethylene has shown considerable promise for similar applications.

Polyimides (PIs)

Available both as thermoplastic and thermoset resins, PIs are a family of some of the most heat- and fire-resistant polymers known. Moldings and laminates are generally based on thermoset resins, although some are made from thermoplastic grades. Unlike most plastics, PIs are available as laminates and shapes, molded parts, and stock shapes from some material producers. Thin-film products—enamel, adhesives, and coatings—are usually derived from thermoplastic PI resins.

Laminates are based on continuous reinforcements including woven glass and quartz fabrics or fibers of graphite, boron, quartz, or organic materials. Molding compounds, on the other hand, contain discrete fibers such as chopped glass or asbestos or particulate fillers such as graphite powders, MoS₂, or polytetrafluoroethylene (PTFE).

PI films and wire enamels are generally unfilled. Coatings may be pigmented or filled with particles such as PTFE for lubricity. Most adhesives contain aluminum powder to provide a closer match to the thermal expansion characteristics of metal substrates and to improve heat dissipation.

PI parts are fabricated by techniques that ranged from powder-metallurgy methods to conventional injection, transfer, and compression molding and extrusion methods. Porous PI parts are also available. Generally, those compounds that are the most difficult to fabricate have the highest heat resistance.

Properties

PI parts and laminates can serve continuously in air at 260°C; service temperature for intermittent exposure can range from cryogenic to as high as 482°C. Glass-fiber-reinforced versions retain over 70% of their flexural strength and modulus at 249°C. Creep is almost nonexistent, even at high temperatures, and deformation under load (27.2 MPa) is less than 0.05% at room temperature for 24 h.

These materials have good wear resistance and low coefficients of friction, both of which are further improved by PTFE fillers. Self-lubricating parts containing graphite powders have flexural strengths above 68 MPa, which is considerably higher than those of typical thermoplastic bearing compounds.

Electrical properties of PI moldings are outstanding over a wide range of temperature and humidity conditions.

PI parts are unaffected by exposure to dilute acids, aromatic and aliphatic hydrocarbons, esters, ethers, alcohols, Freons, hydraulic fluids, JP-4 fuel, and kerosene. They are attacked, however, by dilute alkalis and concentrated inorganic acids.

PI adhesives maintain useful properties for over 12,000 h at 260°C, 9,000 h at 302°C, 500 h at 343°C, and 100 h at 371°C. Resistance of these adhesives to combined heat (to 302°C) and salt-water exposure is excellent.

PI is similar to a polyamide, differing only in the number of hydrogen molecules contained in the groupings. This polymer is suitable for use as a binder or adhesive, and its exceptional thermomechanical properties make it suitable for many high-temperature applications. See also *thermoplastic polyimides*.

Polyketones

Polyketones are partially crystalline engineering thermoplastics that can be used at high temperatures. They also have excellent chemical resistance, high strength, and excellent resistance to burning. Although they require high melting temperatures, polyketones can be extruded and injection-molded with standard processing equipment.

Several polyketones are commercially available:

- Polyaryletherketones, repeating ether and ketone groups combined by phenyl rings (PAEK or PEK).
- Polyetheretherketones, repeating monomers of two ether groups and a ketone group (PEEK).
- Polyetherketoneketones, repeating monomers of one ether group and two ketone groups (PEKK).

In addition, other materials with various combinations of the ether and ketone groups are designed to provide a balance of high heat resistance and good processability, for example, poly[ether][ketone][ether][ketone][ketone].

Polyketone resins are available as natural resins and glass- or carbon-fiber-reinforced and mineral-filled grades.

Properties

Glass transition temperatures (T_g) and melting temperatures (T_m) for polyketones depend on the ratio of ketone to ether groups. With increasing ether groups, both temperatures decrease. With increasing ketone groups, the temperatures go up. The polyether ether ketone (PEEK) T_g is 148°C and its T_m is 335°C, the polyaryletherketone T_g is 190°C and its T_m 380°C, and PEKEEK has a T_g of 177°C and a T_m of 375°C.

Polyketones are stronger and more rigid than most other engineering plastics. They are tough and impact resistant over a wide range of temperatures. Polyketones have very high fatigue strength. Both coefficients of friction and wear rates for polyketones are very low.

The thermal oxidative stability of polyketones is excellent. Typically, continuous-use temperatures are above 249°C (i.e., 50% of strength and rigidity are retained up to this temperature). Moduli of polyketones remain almost constant until the temperature is close to the T_g . Polyketones have comparatively low thermal coefficients of linear expansion. Polyketones have excellent resistance to burning and very low flame spread. These materials have good dielectric properties, with high volume and surface resistivities, and high dielectric strength.

Polyketones are extremely resistant to numerous inorganic and organic chemicals. They are dissolved or decomposed by concentrated, anhydrous, or strong oxidizing acids. Common solvents do not attack polyketones even at elevated temperatures. They have very good resistance to hydrolysis, even in hot water. Like most plastics composed of aromatic building blocks, polyketones are affected by ultraviolet radiation. Polyketones of extremely high resistance to beta rays, gamma rays, and x-rays over a wide range of temperatures.

Processing

Applicable processing methods are injection molding, extrusion, rotational molding, and powder coating. Conventional injection-molding machines can be used with polyketones. Melting temperatures for polyketones vary depending on the resin type. PEK melting temperatures range from 390°C to 430°C; for PEEK, the range is 380°C–399°C. Molding temperatures from 186°C to 216°C are

recommended for molding PEK, and 180°C–198°C for PEEK. Parts for high-temperature applications should be molded at the high end of the temperature range.

Polyketones can be extruded to form sheet, cast film, stock for machining, and wire coatings. Typical melting temperatures for extrusion are 399°C–430°C.

Polyketone parts can be assembled using various adhesives and welding techniques. The adhesives can be epoxies, cyanoacrylates, polyurethanes, or silicones. Welding techniques include heated-tool welding (399°C–538°C for 10–90 s), spin welding, hot-air welding (449°C–499°C), and ultrasonic welding.

Polymer

The terms *polymer*, *high polymer*, *macromolecule*, and *giant molecule* are used to designate high-molecular-weight materials of either synthetic or natural origin. Plastics are relatively stiff at room temperature, rubbers or elastomers are flexible and retract quickly after stretching, and fibers are especially strong filamentary materials. Coatings are generally either plastics or rubbers that have been applied as a thin layer on a substrate. In practice, plastics, rubbers, fibers, and coatings are used as formulations of the polymers with other ingredients such as fillers, pigments, plasticizers, flow improvers, and stabilizers against aging and degradation.

Historical Development

The first modified natural polymers, cellulose nitrate and casein-formaldehyde, were commercially produced about 1860, and the first fully synthetic polymer, phenol formaldehyde was made about 1910. The major development of present polymer science and technology has taken place since about 1920.

Interest in the synthesis of products similar to natural products but possessing more useful properties has been continually stimulated by the successful synthesis of polyamide fibers and rubbers equivalent to natural rubber and by increasing understanding of the nature of proteins, nucleoproteins, carbohydrates, and enzymes in living tissues.

Several striking advances have been the development of cheap raw materials for plastics and other new polymerization processes, and remarkable advances in understanding the relationships among molecular structure, morphology, and physical and chemical behavior. As properties have been improved, plastics have been developed that can be readily and economically fabricated and that can be used for hitherto inappropriate engineering purposes such as gears, bearings, and structural members. Such engineering plastics may frequently be used advantageously to replace metals or other materials.

There has been considerable interest in polymers that can withstand even more extreme environments or possess other specialized properties, for use under the sea, in space, and in biological systems. These interests have emphasized the continuing need for still deeper understanding of bonding (in organic, inorganic, an organic-inorganic systems) and of the implications of bonding and structure to morphology and, in turn, to the overall response to applied stresses and given environments.

A structure that can be represented by a repeated small unit the mer which is a high molecular weight compound, natural or synthetic. Examples include polyethylene, rubber, and cellulose. Synthetic polymers are formed by addition or condensation polymerization of monomers. Some polymers are *elastomers*, some are *plastics*, and some are *fibers*. When two or more dissimilar monomers are involved, the product is called a copolymer. The chain lengths of commercial thermoplastics vary from ~1,000 to > 100,000 repeating units. Thermosetting polymers approach infinity after curing, but

P

their resin precursors, often called prepolymers, may be relatively short—6 to 100 repeating units—before curing. The lengths of polymer chains, usually measured by molecular weight, have very significant effects on the performance properties of plastics and profound effects on processability.

Properties

The properties of polymeric materials are determined by the molecular properties of the macromolecules, the morphology, and the type of formulation involving plasticizers or fillers. The morphology in turn depends on the conditions of fabrication in which molecular orientation or crystallization may be induced. Properties also depend on the temperature and elapsed time of the measurement.

Environmental Stability

The stability of a polymer depends on the chemical nature, on morphology, and on molecular properties. Thus, polyamides are susceptible to hydrolysis on long exposures to dilute acids at high temperatures. Resistance to high temperatures under oxidizing conditions is enhanced by minimizing the hydrogen content, by increasing the molecular softness, and by increasing the content of aromatic structures or heterocyclic rings.

Compounding

Plastic masses, rubber formulations, coatings, and other polymeric compositions may contain age inhibitors and strengthening and coloring pigments, flow improvers, and plasticizers or softening agents. Roll mill, sigma blade, and dough mixers are generally employed to mix the resin with plasticizers and pigments at temperatures usually between 50°C and 250°C.

Additives

The addition of plasticizers to a polymeric material causes it to be softer and more rubbery in character. Plasticizers are held in association with the polymer chains by secondary valence forces. They separate the molecules, thus reducing the effective intermolecular attractive forces.

Age inhibitors are almost always incorporated in polymeric compositions. Oxygen, ozone, light, and electric discharge produce free radicals that cause degradation of the polymer chains. Free-radical inhibitors and light-masking agents are therefore commonly used.

Polyblends

These are produced by the addition of small amounts of a rubbery polymer to a polymeric glass. The impact strength of the glass thus is substantially increased. The rubbery polymer is not truly compatible and exists as a finely dispersed separate phase. Interpenetrating polymer networks, in which two different networks are intertwined, constitute an interesting special case of polyblends. The phenomenon has somewhat similar counterparts in inorganic glass technology and in physical metallurgy. The study of polyblends combines the rigor of physics, for example, fracture mechanics, with organic in physical chemistry and the engineering behavior of the systems of interest.

Fabrication

Polymer formulations can be fabricated into useful forms or articles by a variety of methods.

In the use of molded thermosetting compositions in which heat and pressure are required for the production of solid articles, some form of compression molding is usually employed. The physically compacted composition containing the resin in the fusible stage is forced into a mold cavity of the desired shape and is held under heat and pressure until the curing or vulcanization is complete. When high-pressure is not required, as in the preparation of epoxy compositions and polyester-styrene-glass fiber compounds, it is desirable to use moderate pressure to obtain a uniform molding.

Various forms of injection molding are used for the shaping of thermoplastic (permanently fusible) compositions. The composition is first softened temporarily by forcing the compounded resin granules through a heated chamber, after which it is driven into a relatively cold mold. Under proper conditions, the resin remains soft long enough to fill the mold completely and then rapidly hardens as it cools. The injection molding of engineering plastics often makes it possible to replace an assembly of metal parts by one plastic piece. Variations of the injection molding process are used in the extrusion of films, rods, and pipe and in the spinning of fibers.

Blow molding, a process in which air is blown into a hot tube held in a mold, is used for the manufacture of bottles and other shapes. Certain articles are molded conveniently by rotating a hot mold filled with resin.

In extrusion, a hot melt is forced through a die with an opening shape to produce the cross section desired. Extrusion and molding techniques may be combined to form foams into sheets and other shapes.

Films are also produced by extrusion of a tube into which air is forced. The process is called bubble extrusion. The pipe expands because of the air pressure, to a wall thickness equivalent to the film thickness desired. The walls of the expanded bubble are pressed together in nip rolls, and later the large, thin-walled, collapsed pipe is slipped to yield flat film. Films and sheets are also produced by calendaring; in this process, the hot resin is forced between tightly fitted rolls.

A technique useful for shaping sheets into various shapes is thermoforming, in which a heated sheet is forced against the contours of a mold by a positive pressure or vacuum.

In the casting process, fluid compositions are poured into molds of the desired shape and then allowed to cool or cure. This process is used for the production of foams and in encapsulation, such as in the protection of electronic components or the mounting of biological specimens. In broad terms, coating, slush molding, and painting may be considered to be casting operations.

Some polymers can be formed by methods similar to those used in metallurgical forming. Forging and cold forming are adaptable to the mass production of an increasing number of plastics. Sintering techniques and variations are also used for coating metals and forming polymers that cannot be formed by conventional processes.

In the shaping of thermoplastics particularly, the conditions of molding (temperature, time, and pressure) have a marked effect on the properties of the final product. Uneven cooling produces strains and the flow of the plasticized resin can cause some orientation of the molecules. In bubble molding of film, biaxial orientation is produced. In the drawing of films and fibers, either uniaxial or biaxial orientation may be obtained with equipment similar to the tents used in the textile industry. Orientation results in a substantial increase in the strength of the product in the direction of stretching; in many polymers, crystallization is induced during cold-drawing or stretching. On occasion, discontinuities or areas of strain are produced by partially orienting the molecules, and the product becomes more subject to stress cracking in the presence of solvents or other agents. Thus, the optimum condition of a product results from a judicious combination of mechanical treatment and thermal annealing.

Polymeric Composite

A polymeric composite is any of the combinations or compositions that comprise two or more materials as separate phases, at least one of which is a polymer. By combining a polymer with another material, such as glass, carbon, or another polymer, it is often possible to obtain unique combinations or levels of properties. Typical examples of synthetic polymeric composites include glass-, carbon-, or polymer-fiber-reinforced thermoplastic or thermosetting resins, carbon-reinforced rubber, polymer blends, silica- or mica-reinforced resins, and polymer-bonded or polymer-impregnated concrete or wood. It is also often useful to consider as composites such materials as coatings (pigment-binder combinations) and crystalline polymers (crystallites in a polymer matrix). Typical naturally occurring composites include wood (cellulosic fibers bonded with lignin) and bone (minerals bonded with collagen). On the other hand, polymeric compositions compounded with a plasticizer or very low proportions of pigments or processing aids are not ordinarily considered composites.

Typically, the goal was to improve strength, stiffness, or toughness, or dimensional stability by embedding particles or fibers in a matrix or binding phase. A second goal is to use inexpensive, readily available fillers to extend a more expensive or scarce resin; this goal is increasingly important as petroleum supplies become costlier and less reliable. Still other applications include use of some fillers such as glass spheres to improve processability, the incorporation of dry-lubricant particles such as molybdenum sulfide to make a self-lubricating bearing, and the use of fillers to reduce permeability.

Emphasis on the development of the polymeric composites has been stimulated by the need for greatly improved mechanical and environmental behavior, especially on a strength- or stiffness-to-weight basis. Such composites are also often more efficient in their energy requirements for production than traditional materials. The high absolute and specific (per unit of weight) values of properties such as strength and stiffness have made composites ideal candidates for new applications in aircraft and boats, in passenger vehicles and farm equipment, and in machinery tools and appliances. Composites based on chemically resistant matrixes are used in chemical process equipment.

Mechanical Properties

The behavior of composites depends on the volume fractions of the phases, their shape, and the nature of the constituents and their interfaces. With anisotropic phases, the orientation with respect to the direction of stressing or exposure to permeants is also important. In general, given an appropriate preferred direction, the greater the anisotropy, the greater the effect on a given property, at least up to some point. Thus, all high-modulus reinforcements will stiffen a lower-modulus matrix, but fibers and platelets are more effective than spheres; a similar role of shape holds for the ability to reduce permeability at right angles to the anisotropic particles. Anisotropic high-modulus inclusions invariably increase strength if adhesion is good, but the effect is more complex with particulate fillers such as spheres. Rubbery inclusions lower the stiffness of a high-modulus matrix, but may enhance toughness by stimulating a combination of localized crazing and shear deformation.

Many fibers, for example, glass and carbon, are very stiff and strong. However, the maximum strength of these brittle materials cannot be realized in practical objects because of a high sensitivity to the inevitable small cracks and flaws that are ordinarily present. Most polymers are much less sensitive to such flaws, even though they are inherently less strong. More energy is needed to fracture a

polymer than a ceramic or glass, and a crack tends to grow much less readily in a polymer.

If, for example, the mass of a strong but flaw-sensitive ceramic or glass is divided into many parts, typically into a fiber, and embedded in a polymer matrix, a growing crack may break one fiber, but its progress may be hindered by the matrix or diverted along the interfaces. Thus, even though the matrix contributes only insignificantly to the total strength, it permits a closer approach to the theoretical maximum strength of the glass. Similar considerations apply to short fibers and, with some qualifications, to other forms of reinforcement.

The matrix has several other functions besides the dissipation of energy, which would otherwise cause a catastrophic failure. It protects the fiber against damage by mechanical action, such as rubbing, or by environmental agents, such as water. It must also transfer an applied stress or force to the filament so that they, being much stronger, can bear most of the load. To transfer the stress, the matrix must adhere well to the fiber, although the optimum strength of the interfacial bond desired may vary depending on the application.

The strength of such a composite depends on the orientation of the fibers with respect to the applied force and on the nature of the stress (tensile or compressive). In the selection of materials and design for a composite, the ultimate application must be known. For example, strength of a composite based on longitudinal aligned fibers will be greatest in the direction of the fibers. Rupture under tension will require the pulling out of many fibers; this implies a fiber matrix bond that can yield fairly readily and in yielding increase the energy required for rupture in compression. On the other hand, a stronger interfacial bond is needed to prevent buckling. Compromises in design are often necessary. Thus, at the expense of some strength, fibers are often crisscrossed to minimize the directionality of strength.

Reinforced Thermosetting Resins

The most common fiber-reinforced polymer composites are based on glass fibers, cloth, mat, or roving embedded in a matrix of an epoxy or polyester resin. Usually, the glass surface is treated with a coupling agent to promote adhesion to the matrix. Fabrication may be affected in several ways. Frequently resin-dipped continuous filaments are wound on a mandrel in one of several patterns. Tapes or bundles of fiber coated with resin can also be positioned by hand or machine in layers or pulled through a die. After the desired shape is obtained, curing is affected under heat and pressure.

Boron, polyaramids, and especially carbon fibers confer especially high levels of strength and stiffness. Hybrid fiber combinations, for example, glass with carbon, are often used to achieve a desired balance between cost and performance.

Some examples of properties for several experimental composites (unidirectional fibers) in comparison with metals are striking. In fact, the relative properties of the polymer composites can exceed those of other materials (see *McGraw-Hill Encyclopedia of Science and Technology*, 8th edn., Vol. 14, McGraw-Hill, New York, p. 182; edited by M.M. Schwartz.). Although stiffness is less favorable for glass-fiber composites, carbon-fiber composites have a relative stiffness five times that of steel. Because of these excellent properties, many applications are uniquely suited for epoxy and polyester composites, such as components in new jet aircraft, parts for automobiles, boat hulls, rocket motor cases, and chemical reaction vessels.

Reinforced Thermoplastic Resins

Although the most dramatic properties are found with reinforced thermosetting resins such as epoxy and polyester resins, significant

P

improvements can be obtained with many thermoplastics. Usually short fibers of glass are used—about 3–50 mm in length.

Nylon resins are particularly acceptable. Reinforcements of nylon-6,10 with 20% fiber glass raises the tensile strength and heat-deflection temperature from 59 to 138 MPa and from 150°C to 210°C.

Polycarbonates, acetals, polyethylene, and polyesters are among the resins available as glass-reinforced composition.

The combination of inexpensive, one-step fabrication, by injection molding, with improved properties has made it possible for reinforced thermoplastics to replace metals in many applications in appliances, instruments, automobiles, and tools.

Other Composites

In the development of other composite systems, various matrices are possible; for example, polyimide resins are excellent matrices for glass fibers and give a high-performance composite. Different fibers are of potential interest, including polymers (such as polyvinyl alcohol), single-crystal ceramic whiskers (such as sapphire), and various metallic fibers.

Polymer Matrix

The resin portion of a reinforced or filled plastic. See also *resin-matrix composites*.

Polymeric Transflective Materials

These materials consist of hundreds or more of alternating co-extruded layers of two dissimilar, optically clear thermoplastics, such as acrylic and polycarbonate, for light management and decorative effects. Developed by Dow Plastics, they are referred to as *transflective materials* because they simultaneously transmit and reflect light. The composite structure provides a reflective surface ranging from diffuse to spectral or mirrorlike. Changes to the front and back layers create various effects, such as pearlescence.

Polymerization

(1) Polymerization is the linking of small molecules (monomers) to make larger molecules. Polymerization requires that each small molecule have at least two reaction points or functional groups. There are two distinct major types of polymerization processes: condensation polymerization, in which the chain growth is accompanied by elimination of small molecules such as water or methanol, and addition polymerization, in which the polymer is formed without the loss of other materials. (2) A chemical reaction in which the molecules of a *monomer* are linked together to form large molecules with a molecular weight that is a multiple of the molecular weight of the original substance. When two or more monomers are involved, the process is called copolymerization. (3) The forming creates extended chains and cross-links.

Polymethyl Methacrylate

A thermoplastic polymer synthesized from methyl methacrylate. It is a transparent solid with exceptional optical properties. Available in the form of sheets, granules, solutions, and emulsions, it is used as facing material in certain composite constructions. See also *acrylic plastic*.

Polymorph

In crystallography, one crystal form of a polymorphic material. See also *polymorphism*.

Polymorphism

A general term for the ability of a solid to exist in more than one form. In metals, alloys, and similar substances, this usually means the ability to exist in two or more crystal structures or in an amorphous state and at least one crystal structure. See also *allotropy*, *enantiotropy*, and *monotropism*.

Polyol

An alcohol having many hydroxyl groups. Also known as polyhydric alcohol or polyalcohol. In cellular plastic usage, the term includes compounds containing alcoholic hydroxyl groups such as polyethers, glycols, polyesters, and castor oil used in urethane foams, and other polyurethanes. See also *alcohols*.

Polyolefin Resins

These resins are polymers derived from hydrocarbon molecules that possess one or more alkenyl (or olefinic) groups. The term *polyolefin* typically is applied to polymers derived from ethylene, propylene, and other alpha-olefins, isobutylene, cyclic olefins, and butadiene and other diolefins. Polymers produced from other olefinic monomers, such as styrene, vinyl chloride, and tetrafluoroethylene, generally are considered separately.

Polyolefin homopolymers are made from ethylene, propylene, butylene, and methyl pentene. Other olefinic monomers such as pentene and hexane are used to make copolymers.

Because the chemical and electrical properties of all olefins are similar, they often compete for the same applications. They differ from each other primarily in their crystalline structure. However, since strength properties vary with the type and degree of crystallinity, the tensile, flexural, and impact strength of each polyolefin may be quite different. Stress-crack resistance and useful temperature range also vary with crystalline structure.

In addition to the solid polyolefin resins, these materials are also available as beads from which very low density (1.25–5.0 lb/ft³) foam shapes and blocks are produced. Resilience and energy-absorption properties of these products are exceptional compared with those of conventional polystyrene foams. Polymers available as moldable beads include polyethylene, polypropylene (PP), and a polyethylene/polystyrene copolymer alloy.

The bead forms can be processed by the same methods used for expandable polystyrene. After the beads are expanded (20–40 times that of the solid resin) and conditioned, they are poured into a mold and heated; usually by direct injection of steam. This softens, expands further, and fuses the particles together, forming a uniform, void-free, closed-cell shape. After molding, the shapes are usually annealed by being stored at 49°C–71°C to stabilize shape and dimensions.

Because they contain 80%–95% air by volume, the foamed shapes are not nearly as strong as solid moldings. They are used primarily to cushion impact, insulate thermally, and provide high stiffness-to-weight core materials and composite components. An important application for PP foam is in bumper cores for automobiles. A 76–102 mm thick section of foam at 2–4 lb/ft³ can absorb the energy of a 5 mph impact. Package cushioning for fragile and

valuable products such as electronic or audio components is another application for either polyethylene or PP foam. The toughness of polyethylene/polystyrene alloy foams qualifies them for material-handling applications where repeated use is required.

The principal resins of the polyolefin family are polyethylene and PP. Other polyolefin polymers and copolymers are ethylene-vinyl acetate, ionomer, polybutylene, and polymethyl pentene.

Polyoxymethylene

Acetal plastics based on polymers in which oxymethylene is essentially the sole repeating structural unit in the chains. See also *acetal resins*.

Polyphenylene Ether (PPE)

Alloys, or blends of PPE and polystyrene in various proportions, are marketed under the trade names of *Noryl* and *Prevex*. The resins are processed by conventional injection-molding, or extruding, and thermoforming methods. Structural-foam parts are processed in standard foam-molding systems, using either direct induction of nitrogen gas or conventional chemical blowing agents.

PPE is produced by a process based on oxidative coupling of phenolic monomers. The result, a resin that has good mechanical properties and thermal stability, is then blended with a polystyrene to improve processability. Available grades of molding resins include glass-reinforced and platable compounds and heat-resistant grades (containing nylon), in addition to extrusion and foamable grades. All resins can be furnished in a wide range of colors.

Properties

PPE blends are characterized by outstanding dimensional stability, the lowest water absorption of the engineering thermoplastics, broad temperature ranges, excellent mechanical and thermal properties, and excellent dielectric properties over a wide range of frequencies and temperatures.

Because of their excellent hydrolytic stability, both at room and elevated temperatures, PPE blend parts can be repeatedly steam-sterilized with no significant change in properties. In exposure to aqueous environments, dimensional changes are low and predictable. Resistance to acids, bases, and detergents is excellent. The material is attacked, however, by many halogenated or aromatic hydrocarbons. Prototype testing of components requiring exposure to such environments is recommended.

Polyphenylene Oxide

Polyphenylene oxide is a plastic that is notable for its high strength and broad temperature resistance. There are two major types: phenylene oxide (PPO) and modified phenylene oxide (Noryl). These materials have a deflection temperature ranging from 100°C to 174°C at 2 MPa. Their coefficients of linear thermal expansion are among the lowest for engineering thermoplastics. Room-temperature strength and modulus of elasticity are high and creep is low. In addition, they have good electrical resistivity. Their ability to withstand steam sterilization and their hydrolytic stability make them suitable for medical instruments, electric dishwashers, and food dispensers. They are also used in the electrical or electronic fields and for business machine housings.

Tensile strength and modulus of phenylene oxides rank high among engineering thermoplastics. They are processed by injection-molding, extrusion, and thermoforming techniques. The foam

grades, with their high rigidity, are suitable for large structural parts. Because of good dimensional stability at high temperatures and under moisture conditions, these plastics are readily plated without blistering. Also known as *polyphenylene ether*.

Polyphenylene Sulfide (PPS)

PPS is a crystalline, high-performance engineering thermoplastic characterized by outstanding high-temperature stability, inherent flame resistance, and broad chemical resistance. PPS resins and compounds manufactured in the United States are trade named *Ryton*.

A wide range of injection-molding grades of PPS is available. The series with various glass-fiber levels (designated R-3, R-4, and R-5) is recommended for mechanical electronic applications requiring high mechanical strength, impact resistance, and insulating characteristics. All other compounds contain various mineral fillers in addition to glass-fiber reinforcement. Ryton R-7 and R-8 are suitable for electrical applications requiring high arc resistance and low arc tracking. The R-10 series of pigmented compounds include several grades suitable for support of current-carrying parts in electrical components. PPS is essentially transparent to microwave radiation, so the R-11 series is suited specifically for microwave ovenware and appliance components.

Unreinforced PPS resins are also available as powders for slurry coating and electrostatic spraying. The resin coatings are suitable for food-contact applications as well as for chemical-processing equipment.

The injection-moldable PPS compounds require processing temperature of 316°C–343°C. Molding temperatures can range from 37.8°C to 135°C to control the crystallinity. Cold-molded parts deliver optimum mechanical strength, and hot-molded highly crystalline parts provide optimum dimensional stability at high temperatures.

PPS is also available in long-fiber-reinforced forms. One type, called stampable sheet, contains fiber-mat reinforcement for processing by compression molding. The other form contains reinforcement and is designed for laminating and thermoforming. Reinforcement in both forms can be glass or carbon fiber.

Properties

Most PPS compounds are used for their combination of high-temperature stability, chemical resistance, dimensional reliability, and flame retardancy. The compounds all have excellent stability at very high temperatures. Underwriters Laboratories (UL) temperature index is 200°C–240°C, depending on compound, thickness, and end use. In short-term excursions, the compounds have heat-deflection temperatures of 260°C or higher, depending on the crystallinity of the molding. Mechanical strength of the compounds remains high at high temperatures. For example, the flexural modulus of Ryton R-4 is as high as 260°C as that of ABS (acrylonitrile, butadiene, styrene) at room temperature.

PPS has excellent resistance to a broad variety of chemicals, even at high temperatures. In fact, the resin has no known solvent below 204°C. The resins are flame retardant without additives (UL 94V-0/5). The oxygen index of the resin is 44, and indices of the compounds range from 47 to 53. Because flame retardancy is inherent, regrind is as flame resistant as virgin material.

Mechanical properties of the various PPS compounds are tailored for target applications. The balance of properties can be controlled by the degree of crystallinity of a molded part. Amorphous moldings have optimum mechanical strength at room temperature, and crystalline moldings deliver optimum dimensional stability at high temperatures.

P

Applications

A metal plate spins at 7200 rpm inside a computer's hard disk drive. Less than three virus widths above that surface resides a rock-hard ceramic block on the end of an aluminum arm. The temperature inside is 260°C–316°C. Under these conditions, a new grade of PPS, Ryton, R-4-230 NA, provided connectors with the proper electrical insulation, dimensional stability, flame retardancy, rigidity, and creep resistance for the drives. It is also a material that would not outgas inside the drives.

The Ryton PPS stiffness and creep resistance also make the material ideal for load-bearing applications, such as the actuator latch and stop.

Polyphthalamide (PPA)

PPA is a family of semicrystalline thermoplastics of Amoco Performance Products, with the trade name *Amodel*, having advantages over conventional nylons in resistance to humidity, auto fuels, water/glycol mixtures, and heat. The melting temperature is 590°F (310°C), and unreinforced, the resin has a specific gravity of 1.17%, 24 h water absorption of 0.81%, a tensile yield strength of 104 MPa, a flexural modulus of 3275 MPa, a heat-deflection temperature of 248°F (120°C) at 1.8 MPa, and Izod notched impact strength of 53 J/m. An extra-tough grade is slightly lighter in weight, less water absorbent (0.65%), and considerably less strong and rigid, but has an impact strength of 1068 J/m. *Thermocomp UF-1006*, of LNP Engineering Plastics, is a 30% glass-reinforced grade based on Amodel. RTP Co. makes a line of lubricated compounds based on PPA for gears and bearings. Polytetrafluoroethylene and/or silicone serve as lubricants and glass, carbon, and/or aramid fibers as reinforcements. And *RTP 4000* grade with 15% aramid fiber, 14% PTFE, and 10% silicone is the most wear resistant.

Polypropylene (PP) Plastics

PP is made by polymerization of propylene using catalysts and similar to the low-pressure polymerization of ethylene. It is a linear polymer, more than 95% of which has a spatially ordered structure. The commercial polymer contains over 99% C_3H_6 , with the remainder stabilizing additives. Molded pieces or molding pellets of unpigmented material may be identified by density (0.905) and by maximum crystalline melting point (168°C–170°C).

Produced from propylene gas, PP resins are semitranslucent and milky white in color and have excellent colorability. Most PP parts are produced by injection molding, blow molding, or extrusion of either unmodified or reinforced compounds. Other applicable processes are structural-foam molding and solid-phase and hot-flow stamping of glass-reinforced sheet stock (a product of *Azdel*).

PP plastics are an important group of synthetic plastics employed for molding resins, film, and texture fibers. Propylene is a methyl ethylene, $CH_3CH:CH_2$, and is produced in the cracking of petroleum. It belongs to the class of unsaturated hydrocarbons known as olefins, which are designated by the word ending *-ene*. Thus, propylene is known as propene as distinct from propane, the corresponding saturated compound of the group of alkanes from petroleum and natural gas. These unsaturated hydrocarbons tend to polymerize and form gums and are thus not used in fuels although they have antiknock properties.

Properties

PP is a low-density resin that offers a good balance of thermal, chemical, and electrical properties, along with moderate strength

and moderate cost. Strength properties are increased significantly with glass-fiber reinforcement. Increased toughness is provided in special, high-molecular-weight, rubber-modified grades.

Electrical properties of PP moldings are affected to varying degrees by service temperature. Dielectric constant is essentially unchanged, but dielectric strength increases and volume resistivity decreases with increased temperature.

PP has limited heat resistance, but heat-stabilized grades are available for applications requiring prolonged use at elevated temperatures. Useful life of parts molded from such grades may be as long as 5 years at 121°C, 10 years at 110°C, and 20 years at 99°C. Specially stabilized grades are rated by Underwriters Laboratories at 120°C for continuous service.

PP resins are unstable in the presence of oxidative conditions and ultraviolet (UV) radiation. Although all grades are stabilized to some extent, specific stabilization systems are often used to suit a formulation for a particular environment. PPs resist chemical attack and staining and are unaffected by aqueous solutions of inorganic salts or mineral acids and bases, even at high temperatures. They are not attacked by most organic chemicals, and there is no solvent for the resin at room temperature. The resins are attacked, however, by halogens, fuming nitric acid, and other active oxidizing agents and by aromatic and chlorinated hydrocarbons at high temperatures.

Polypropylenes is low in weight. The molded plastic has a density of 0.910; a tensile strength of 34 MPa, with an elongation of 150%; and hardness of Rockwell R95. The dielectric strength is 59×10^6 V/m, dielectric constant 2.3, and softening point 150°C. Blow-molded bottles of PP have good clarity and are nontoxic. The melt flow is superior to that of ethylene. A unique property is their ability in thin sections to withstand prolonged flexing. This characteristic has made PPs popular for "living hinge" applications. In tests, they have been flexed over 70 million times without failure.

Molecular Types

In PP plastics, each carbon atom linked in the molecular chains between CH_2 units has a CH_3 and an H attached as side links, with the bulky side group spiraled regularly around the closely packed chain. The resulting plastic has a crystalline structure with increased hardness and toughness and a higher melting point. This type of stereosymmetric plastic has been called isostatic plastic. It can also be produced with butylene or styrene, and the general term for the plastics is *polyolefins*.

Grades

The many different grades of PPs fall into three basic groups: homopolymers, copolymers, and reinforced and polymer blends. Properties of the homopolymers vary with molecular weight distribution and the degree of crystallinity. Commonly, copolymers are produced by adding other types of olefin monomers to the propylene monomers to improve properties such as low-temperature toughness. PPs are frequently reinforced with glass fibers and fillers to improve mechanical properties and increase resistance to deformation at elevated temperatures. Biaxially oriented polypropylene film (film stretched in two ways) has greatly improved moisture resistance, clarity, and stiffness. It is used for packaging tobacco products, snack foods, baked goods, and pharmaceuticals. Metallized grades also are available for packaging design for extended shelf life.

Foamed PPs include expandable polypropylene (EPP) bead and injection-molded structural foam. EPP provides greater energy absorption and flexibility than expandable polystyrene. Structural PP

foam moldings consist of a solid outer skin and foamed core. They are used to achieve greater stiffness in larger, lightweight parts (strength-to-weight ratios are three to four times greater than solid parts).

PP fiber unless modified is more brittle at low temperatures and has less light stability than polyethylene, but it has about twice the strength of high-density linear polyethylene. Monofilament fibers are used for filter fabrics and have high abrasion resistance and a melting point at 154°C. Multifilament yarns are used for textiles and rope. PP rope is used for marine hawsers, will float on water, and does not absorb water like Manila rope. It has a permanent elongation, or set, of 20%, compared with 19% for nylon and 11% for Manila rope, but the working elasticity is 16%, compared with 25% for nylon and 8% for Manila. The tensile strength of the rope is 406 MPa. Fine-denier multifilament PP yarn for weaving and knitting dyes easily and comes in many colors. Chlorinated PP is used in coatings, paper sizing, and adhesives. It has good heat and light stability, high abrasion resistance, and high chemical resistance.

Fabrication

Compression Molding

This is seldom used with PP except for making heavy slab and multiple daylight presses.

Injection Molding

Standard techniques for molding apply to PP. Cylinder temperatures of 288°C or less, and fast rams operating in the neighborhood of half the available machine pressure, generally give good molding at faster cycles. No special metals are needed for cylinders or molds. Since PP shows a definite change in melt viscosity between 232°C and 274°C, the indicated cylinder temperature should be balanced with the machine heater capacity, the size of each shot, and the cycle time to maintain such melting temperatures.

Molds for PPs should embody the best techniques used with thermoplastics; uniform wall thicknesses; avoidance of heavy ribs, bosses, and fillets; use of channels or curved walls instead of ribs to increase rigidity.

Extrusion

Heavy sheets, shapes, thin film, and monofilament are all being produced commercially by extrusion. Equipment required can be made of the usual steel alloys with no danger of corrosive degradation products. For even melting, screws of length-to-diameter ratio of 20:1 are best.

Uses

PP homopolymer, random copolymer, and impact copolymer resins are tailored for specific polymer applications and fabrication methods and also to achieve desired end-product performance. Low-molecular-weight resins, used for melt-spun and melt-blown fibers and for injection-molding applications, are produced by oxidative degradation of a higher-molecular-weight polymers at elevated temperatures. These materials, often called controlled rheology resins, have narrower molecular weight distributions and lower viscoelasticity. The brittleness of PPs homopolymer, particularly at temperatures below 0°C, is greatly reduced by blending it with ethylene-propylene rubber. Compounding with mineral fillers and glass fibers improves product stiffness and other properties. Higher-stiffness resins also are produced by increasing the stereoregularity of the polymer or by the addition of nucleating agents. PP resins are used in extrusion and blow-molding processes and to make cast, slip, and oriented films. Stabilizers are added to PPs to protect it from

attack by oxygen, UV light, and thermal degradation; other additives improve resin clarity, flame retardancy, or radiation resistance.

New applications for PP include in-line skates. The low-cost gate consists of a boot and frame injection molded as a single unit. Using ACC-TUF PP impact copolymer to make the one-piece skate has produced a significant cost savings, while retaining the performance attributes of the more expensive material. ACCTUF PP impact copolymer was a product line of Amoco Polymers. BP Amoco Accutuf® 3950 impact copolymer PP and a series of PP copolymers however, have been discontinued. It can be ordered under special arrangements.

The copolymer solved the problem of balance between impact resistance and stiffness in thermoplastic materials. Typically, the greater the impact resistance of a material, the less its stiffness. The balance properties of ACC-TUF result in a high degree of toughness, while resisting low-temperature impacts and thermal deformation.

In another application, a PP composite was used to keep boats ice-free; it is used as a submersible circulation unit that is able to keep water around boats and docks from freezing. With a powerful flow of water around a boat or dock, the formation of ice is prevented. The submersible, motor-driven unit features a one-piece plastic shroud made with a long-glass-fiber-reinforced PP composite material.

Because the shroud protects the propeller blade from damage by wood and other debris, a material was needed with excellent strength, stiffness, and impact resistance.

Suspended by two lines over the side of the boat, the D-Icer unit works by continuously propelling warmer subsurface water up to the surface. Because it lies under the water, a material that was available in bright colors for easy visibility was needed. It also had to be UV stabilized so that any UV light that penetrates the water would not destroy it.

In addition, the structural composites have good dimensional stability to help maintain mechanical performance in wet environments. This is important because the shroud forms the upper half of the motor housing, which contains a gasket. The stable material helps prevent leaks. And, most important, it resists subzero temperatures.

Finally, recently introduced TSL snowshoes, made of lightweight, injection-molded PP, combine strength and reliability with a convex shape that prevents snow buildup on either side. Each model offers several other features that ensure trouble-free hiking, even in challenging snow conditions and over difficult terrain. They include steel crampons attached to the shoe base that resists temperatures as low as -20°C for traction on icy or hard-packed snow, radial snow fins that aid walking in deep powder, and a binding system that exhibits excellent grip in transverse or when scrambling up steep slopes.

An assortment of models makes the shoes an easy fit for various users and conditions. For example, the TSL 510 fits children, the TSL 710 adapts to lighter-weight adults or firmer packed snow, the TSL 810 accommodates heavier weights or powder-snow use, and the TSL 225 multipurpose shoe is designed for steep, irregular terrain.

Different bindings also adapt to differing needs. The Trappeur model, a high-strength, expandable rubber shoe, conforms to any kind of boot. The Rando binding, designed for use with hiking, pack, and after-ski boots, features a climbing arc for steep ascents and a heel block for descent and jumping. And the Aventure binding, built for extreme terrains, adapts to mountaineering boots notched in the heel and toe.

Polystyrenes

Polystyrenes comprise one of the largest and most widely used families of plastics. Often called the “workhorse” of the thermoplastics, polystyrenes consist of the basic general-purpose materials, plus a wide variety of modified grades of polymers, copolymers, and blends.

P

All polystyrenes generally have several features in common: (1) low cost, (2) unexcelled electrical insulating properties, (3) virtually unlimited colorability, (4) ability to be made crystal clear (in general-purpose grades), and (5) high hardness and gloss.

Polystyrenes have excellent molding and extrusion characteristics and are formed readily and inexpensively by any of the thermoplastic forming methods. Types available include molding and extrusion grades, foams, sheet and film, and fiber.

Characteristics and Properties

A thermoplastic resin used for molding, in lacquers, and for coatings, polystyrene is formed by the polymerization of the monomeric styrene, which is a colorless liquid of the composition $C_6H_5CH:CH_2$, with a specific gravity of 0.906 and boiling point of 145°C. It is made from ethylene, in which ethylene has one of the hydrogen atoms replaced by a phenyl group. It is also called phenyl ethylene and vinyl benzene. As it can be made by heating cinnamic acid, an acid found in natural balsams and resins, it is also called cinnamene. In the form of vinyl toluene, which consists of mixed isomers of methyl styrene, the material is reacted with drying oils to form alkylid resins for paints and coatings.

The polymerized resin is a transparent solid very light in weight with a specific gravity of 1.054–1.070. The tensile strength is 27–68 MPa, compressive strength 82–117 MPa, and dielectric strength $18\text{--}24 \times 10^6$ V/m. Polystyrene is notable for its water resistance and high dimensional stability. It is also tougher and stronger at low temperatures than most other plastics. It is valued as an electrical insulating material, and the films are used for cable wrapping.

Types

General-Purpose Types

So-called general-purpose polystyrenes are characterized by clarity, luster, colorability, rigidity, unexcelled dielectric properties, and moldability. They are used where rigidity and appearance are important, but where toughness is not required. Typical uses include wall tile, container lids, and brush backs.

Grades are available with a wide range of processing characteristics. Highly heat-resistant types, which also have improved toughness, are available in crystal and a full range of transparent, translucent, and opaque colors.

Impact Grades

To overcome the relatively low impact strength of general-purpose polystyrene, combinations of polystyrene and rubber provide grades whose impact strength depends on the proportion of rubber added. Grades are generally characterized as medium-, high-, and extra-high-impact types. As impact strength increases, rigidity or modulus decreases. Such materials are available in virtually unlimited colors, but cannot reproduce crystal clear.

Medium-impact polystyrenes are used where moderate toughness plus good translucency is required. They are used for such products as containers, closures, and table-model radio cabinets. Types of medium-impact polystyrenes are available with improved heat resistance, surface gloss, and moldability.

High-impact polystyrenes include special grades with improved heat resistance, moldability, and surface gloss. They are used for refrigerator inner-door liners, crisper trays, containers, appliance housings, and toys. Highly heat resistant, high-impact grades (generally suitable for sections greater than 2.2 mm) are used for television masks and housings, portable radio cabinets, auto heater ducts, and automatic washer soap dispensers.

Extra-high-impact strength grades have relatively low moduli about 1360–1700 MPa and are used primarily where resistance to high-speed loading is required.

Chemical-Resistant Grades

Copolymers of styrene and acrylonitrile provide resistance to chemicals such as carbon tetrachloride, aliphatic hydrocarbons, and food stains and provide much better stress-crack resistance than polystyrene. The copolymers are transparent and haze-free, but are slightly yellow; they are available also in a wide variety of colors.

Primary use for the copolymers are in drinking tumblers and cups that have high resistance to crazing by butter fat and staining by coffee oils. Industrial uses include water filter parts, oil filter bowls, storage battery containers, and washing machine parts.

Other Special Grades

Light-stabilized types of styrene-methyl methacrylate copolymers and glass-reinforced molding materials are other special grades of polystyrene.

Light-stabilized grades were developed specifically for applications involving exposure to intense fluorescent light radiation, for example, “egg crate” light diffusers. Such formulations prevent the yellowing that occurs in unstabilized polystyrene when it is exposed to fluorescent light.

Styrene-methyl methacrylate copolymers were developed to provide a material with weatherability approaching that of acrylics, but at a lower cost. They have been used primarily for escutcheons, instrument panels, decorative medallions, brush blocks, auto tail light lenses, and advertising signs.

Glass-reinforced polystyrenes (incorporating chopped glass fibers) are available for injection molding or extrusion and provide higher strength, greater durability, and higher strength at elevated temperatures than do unreinforced polystyrenes.

Styrene can be polymerized with butadiene, acrylonitrile, and other resins. The terpolymer, acrylonitrile-butadiene-styrene (abbreviated ABS), is one of the common combinations. Styrene-acrylonitrile has excellent resistance to acids, bases, salts, and some solvents. It also is among the stiffest of the thermoplastics with a tensile modulus of 2757–3791 MPa. Acrylate-styrene-acrylonitrile has very good weathering resistance (nonyellowing), good toughness, and stress cracking resistance. Styrene-butylene resins are copolymers that mold easily and produce thermoplastic products of low water absorption and good electrical properties. They have strength equal to the vinyls with greater elongation.

Foamed Polystyrene

It is used in many forms, including extruded sheet (which is then thermoformed, e.g., egg cartons, trays); expandable polystyrene beads, which contain a blow agent (usually pentane) and which are processed into low-density foamed products, such as hot- and cold-drink cups and protective packaging; and block and heavy sheet, used for thermal insulation. See also *high-impact polystyrenes*.

Polysulfide Resins

These resins vary in properties from the viscous liquids to rubber-like solids. Organic polysulfide resins are prepared by the condensation of organic dihalides with a polysulfide.

The linear, high-molecular-weight polymers can be cross-linked or cured by reaction with zinc oxide. Compounding and fabrication of the rubbery polymers can be handled on conventional rubber machinery. The polysulfide rubbers are distinguished by their

resistance to solvents such as gasoline and to oxygen and ozone. The polymers are relatively impermeable to gases. The products are used to form coatings that are chemically resistant and special rubber articles, such as gasoline bags.

Applications

The polysulfide rubbers were among the very first commercial synthetic rubbers. Although the products are not as strong as other rubbers, the chemical resistance makes them useful in various applications. The polysulfide rubbers were also among the first polymers to be used in solid-fuel compositions for rockets.

Polysulfide Rubber

Basically, polysulfide rubbers are chemically saturated polymers with reactive terminals through which conversion to a thermoset, elastomeric state can be affected by means of suitable catalysts or curing agents. More specifically, these rubbers are the products of a condensation polymerization in which one or more organic dihalides are reacted with an aqueous solution of sodium polysulfide.

Properties

As with a number of other synthetic elastomers, polysulfide rubbers require reinforcing fillers to achieve optimum physical properties. However, the high tensile values possible with unsaturated rubbers are not obtainable with polysulfides. For practical purposes, values of 10.3–12.4 MPa are the upper maximum limit.

The primary assets of these rubbers are outstanding oil, gasoline, and solvent resistance, as well as very low permeability to gases and solvent vapors. Also because of their saturated structure, polysulfides possess excellent resistance to oxidation, ozone, and weathering. Performance as regards temperature is somewhat dependent on polymer structure, but with few exceptions, the serviceability range is from -51°C to 121°C and intermittently up to 149°C . The principal limitation of polysulfide rubber compounds is relatively low resistance to compression set.

Available Forms

Polysulfide rubbers are novel in that they are available not only as solids but also as liquids. The liquids are 100% polymer, unadulterated with solvents or diluents, which also can be converted to highly elastic rubbers with properties closely approaching those of the cured, solid polysulfides. Viscosities range from a very fluid 5 poise to a heavy molasses-like 700 poise.

Fabrication and Applications

Design with both polysulfide crudes and liquids is quite similar, but because of the difference in physical form, the products made from these materials are processed and fabricated somewhat differently.

Crudes or Solid Polymers

Polysulfide crude rubbers are processed in the same way as other synthetic rubbers, on conventional mixing and fabricating equipment. The incorporation of reinforcing fillers, curing agents, and other additives is accomplished on two roll mills or Banbury-type internal mixers. Subsequent operations such as extruding, calendering, molding, or steam vulcanization can be carried out in the normal manner, except that somewhat closer factory control must be exercised than might be necessary with a larger volume, general-purpose rubbers.

Because polysulfide crudes may be classified as specialty rubber, their use is usually limited to those applications that demand exceptional solvent resistance. Such products include gaskets, washers, diaphragms, various types of oil and gasoline hose, and other mechanical rubber goods items. However, the solvent combinations encountered in various paints, coatings, and inks are responsible for the major consumption of these rubbers. A great number of the rollers employed for can lacquering, wood and metal coating, and the application of quick-drying inks are fabricated with a polysulfide rubber covering. Much of the hose use with hot lacquer and paint spraying equipment is made with a polysulfide tube or inner liner. One other unique commercial use of crudes is in the form of nonhardening putties, which make effective solvent-resistant seals for static type joints.

Liquid Polymers

Liquid polymer compounds are mixed by a three-roll paint mill, colloid mill, ball mill, or internal mixer. The resulting products may be applied by brushing, spraying, casting, or caulking gun depending on the characteristics of the specific compound involved and the type of application for which it was designed. Curing or conversion of these materials to highly elastic rubbers can be accomplished over a relatively wide temperature range, but their ability to cure at room temperature has been a primary factor in the employment of these polymers for a diversity of industrial applications. Despite their similarity in performance properties, there has been little overlapping use of the polysulfide crudes and liquid polymers in the same application areas; however, because of versatility in end-use product fabrication, liquids are threatening to intrude into solid-rubber fields of application.

One of the major uses of liquid polysulfide polymers is in the manufacture of stimulants in the aircraft, building, and marine industries. Such products may be compounded to bond to most building materials and provide flexible, elastic seals for joints that are subject to a high degree of movement and vibration. Curing or conversion to the rubbery state can be regulated to occur in minutes or hours at normal atmospheric temperatures depending on the demands of the application techniques involved.

Other applications include cold-setting casting, potting, and molding compounds, which exhibit flexibility, very low shrinkage, and excellent dimensional stability. The impregnation of leather with polysulfide liquid polymers imparts water and solvent resistance without loss of pliability. The liquid polysulfides may also be employed as coatings and adhesives, but more commonly, they are used as modifiers of epoxy resins for these and many other industrial applications. Modification is chemical rather than physical and results from an addition reaction between the polysulfide thiol terminals and epoxide groups. Greatly improved flexibility and impact resistance, lower shrinkage, less internal strain, better wetting properties, and lower moisture vapor transmission are the advantages gained.

Polysulfone (PSU) Resins

These are plastics whose molecules contain sulfone groups ($-\text{SO}_2-$) to the main chain, as well as a variety of aromatic or aliphatic constituents such as ether or isopropylidene groups. They have been made by reacting bisphenol A and 4,4'-dichlorodiphenylsulfone with potassium hydroxide in dimethyl sulfoxide at 265°F – 285°F (130°C – 140°C). The structure of the polymer is benzene rings or phenylene units linked by three different chemical groups: a sulfone group, an ether linkage, and an isopropylidene group. They may be processed by extrusion, injection molding, or blow molding.

PSUs based on aromatic backbones constitute a useful class of engineering plastics, owing to their high strength, stiffness, and toughness together with high thermal and oxidative stability, low

P

creep, transparency, and the ability to be processed by standard techniques for thermoplastics. Aliphatic PSUs are less stable, for example, to hydrolysis, but are of interest for some biomedical applications. Four major uses of PSUs have been of commercial interest: (1) PSU, (2) polyarylsulfone, (3) polyethersulfone, and (4) polyphenylsulfone.

The aromatic structural elements and the presence of sulfone groups are responsible for the resistance to heat and oxidation; ether and isopropylidene groups contribute some chain flexibility. Aromatic PSUs can be used over wide temperature ranges, to $\sim 150^{\circ}\text{C}$ for PSU and to 200°C for polyethersulfone. In fact, the high-temperature performance of polyethersulfones is surpassed by few other polymers. Resistance to hydrolysis at high temperatures and to most acids, alkalies, and nonpolar organic solvents is excellent; however, the resins may be attacked or dissolved by bipolar solvents, especially if the component is under stress. Although resistance to ionizing radiation is high, protection against ultraviolet light is recommended for outdoor applications. Dimensional stability and electrical properties such as dielectric loss and strength are retained well during service, and flammability as well.

Because of the combination of properties discussed, polyethersulfone resins find many applications in electronic and automotive parts, medical instrumentation subject to sterilization, chemical and food processing equipment, and various plumbing and home appliance items. Coating formulations are also available, as well as grades reinforced with glass beads or fibers.

Polyterephthalate

A thermoplastic polyester in which the terephthalate group is a repeating structural unit in the chain, the terephthalate being greater in amount than other dicarboxylates that may be present.

Polytetrafluoroethylene (PTFE)

PTFE lubricants dispersed into a thermoplastic base resin greatly improve surface-wear characteristics. Molecular weight and particle size of the PTFE lubricant are designed to provide optimum improvements and wear, friction, and *PV* values for selected resin systems. PTFE has the lowest coefficient of friction (0.02) of any known internal lubricant. Its static coefficient of friction is lower than its dynamic coefficient, which accounts for the slip/stick properties associated with PTFE/metal sliding action. During the initial break-in period, the PTFE particles embedded in a thermoplastic matrix shear to form a high-lubricity film over the mating surface. The PTFE cushions asperities from shock and minimizes fatigue failure.

Forms

Glass fibers are frequently used in combination with silicone and PTFE lubricants, which offset the negative wear effects that the glass fibers have on surface characteristics. The use of silicone only, in conjunction with glass fibers, is not recommended; however, PTFE provides far more protection to the mating surface and should be used (with or without silicone) if the wear rate of the mating surface is important.

Uses

The first thermoplastics that were recognized for their inherent lubricity were nylon, acetal, and PTFE. These materials perform well, but for the more critical uses, their coefficients of friction may be too high, or wear may be too rapid.

The next generation of self-lubricated thermoplastics was formulated of various space resins that contained molybdenum disulfide,

graphite, or PTFE particles to improve both lubrication and wear characteristics. Although wear resistance was indeed upgraded considerably, mechanical strength and dimensional stability of these compounds are often insufficient.

To minimize these deficiencies, reinforcing fibers of glass or carbon are added. The resulting composites are several times stronger than the unreinforced materials, and they are extremely stable in a wide range of service environments. But these materials too have a shortcoming: In service, a period of time is required for the internal lubricant to become exposed and to be burnished over the wear surfaces. During this run-in period, as a bearing or wear member is put into service, the unlubricated surfaces are in contact, and damage may occur.

Two approaches to eliminating these problems use silicone fluids to provide the lubrication function.

Thermoplastic composites can also be internally lubricated with a variety of systems to improve wear resistance. PTFE and silicone, separately or in combination, provide the best improvements and wear characteristics. Graphite powder and molybdenum disulfide are also used, primarily in nylons. The PTFE lubricants are specially modified to enhance their lubricious nature in the compound. The optimum level of lubricating filler varies depending on filler type and resin, but typical ranges follow:

PTFE	15%–20%
Silicone	1%–5%
PTFE/silicone	15%–20%
Graphite	10%
MoS ₂	2%–5%

Addition of these lubricants further improves wear characteristics of good bearing materials such as nylon and acetal. The lubricants also allow the use of poor wearing, but close-tolerance materials, such as polycarbonate, in gear or bearing applications. Lubricants can be used by themselves or in conjunction with glass or carbon-fiber reinforcements.

PTFE and silicone fluids; glass, aramid, and carbon fibers; and graphite powder are the primary reinforcements and lubricants used in internally lubricated composites. The composites are based on engineering resins for injection-molded wear and structural parts.

Polyurethanes

Extremely wide variations in forms and in physical and mechanical properties are available in polyurethanes. Grades can range in density from 13.88 g/cm^3 in cellular form, to over 1937.6 g/cm^3 in solid form, and in hardness from rigid solids at 85 Shore D to soft, elastomeric compounds.

Polyurethane polymers, produced by the reaction of polyisocyanates with polyester or polyether-based resins can be either thermoplastic or thermosetting. They have outstanding flex life, cut resistance, and abrasion resistance. Some formulations are as much as 20 times more resistant to abrasion than metals.

The noncellular grades—millable gums and viscous, castable, liquid urethanes—are elastomeric thermoset types, processed by conventional rubber methods.

Processing

There are three major types of polyurethane elastomers. One type is based on ether- or ester-type prepolymers that are chain-extended and cross-linked using polyhydroxyl compounds or amines;

alternatively, the unsaturated groups may be introduced to permit vulcanization with common curing agents such as peroxides. All of these can be processed by methods, commonly used for rubber. A second type is obtained by first casting a mixture of prepolymer with chain-extending and cross-linking agents and then cross-linking further by heating. The third type is prepared by reacting a dihydroxy ester- or ether-type prepolymer, or a diacid, with a diisocyanate such as diphenyl-methane diisocyanate and a diol; these thermoplastic elastomers can be processed on conventional plastics equipment. In general, urethane elastomers are characterized by outstanding mechanical properties and resistance to ozone, although they may be degraded by acids, alkalis, and steam.

A wide variety of tough and abrasion-resistant urethane coatings are available. Many are based on the reaction of castor oil, a triol, with an excess of diisocyanate; the resulting triisocyanate undergoes cross-linking by reaction with atmospheric moisture. Urethane alkyds can also be made by reacting an unsaturated drying oil with glycerol and then reacting the product with a diisocyanate; curing is affected by atmospheric oxidation of the double bonds. Still other coatings are based on the use of prepolymers. Polyurethanes are also used as adhesives, for example, in the bonding of rubber and of nylon.

Foams

Polyurethane foams are thermoset materials that can be made soft and flexible or firm and rigid at equivalent densities. These foams, made from either polyester- or polyether-type compounds, are strong, even at low density, and have good chemical resistance. Polyether-based foams have greater hydrolysis resistance, are easier to process, and cost less. Polyester-based foams have higher mechanical properties, better oil resistance, and more uniform cell structure. Both types can be sprayed, molded, foamed in place, or furnished as sheets cut from slab stock.

Flexible Foams

Glass transition temperatures (the temperature at which an elastomeric material become stiff and brittle) of flexible foams are well below room temperature. The foams can be pigmented to any color, but, regardless of pigmentation, they yellow when exposed to air and light. Some types of flexible foams are excellent liquid-absorbing media and can hold up to 40 times their weight of water.

Polyether-type foams are not affected by high-temperature aging, either wet or dry, but ultraviolet exposure produces brittleness and reduces properties. In use, these foams are always covered with a fabric or other material.

Most solvents and corrosive solutions decrease tear resistance and tensile strength and cause swelling of flexible foams. Swelling is not permanent, however, if the solvent is removed and the foam dried. However, the foams can be destroyed by strong oxidizing agents and hydrolyzed in strong acids or bases. Generally, the polyether foams are more resistant to hydrolytic degradation; the polyester foams are more resistant to oxidative attack.

Applications for polyester flexible urethane foam include gasketing, air filters, sound-absorbing elements, and clothing interliners (laminated to a textile material). The polyether types are used in automobile and recreational-vehicle seats, carpet underlay, furniture upholstery, bedding, and packaging.

Rigid Foams

Bases for rigid foams are polymers having glass transition temperatures higher than room temperature. The cells of rigid foam are about the same size and uniformity as those of flexible foam, but rigid foams usually consist of 90% closed cells. For this reason,

water absorption is low. Compressing the foam beyond its elastic limit damages the cellular structure.

Rigid foams are blown with either carbon dioxide or fluorocarbons. Gas generated by vaporization of fluorocarbons, entrapped in the closed cells, gives the foam a very low thermal conductivity of 0.11–0.14 Btu in./h ft² °F. Conductivity increases with age, however, to a constant value of about 0.16.

Rigid urethane foams are used for thermal insulation of refrigerators, refrigerated trucks and railroad cars, cold-storage warehouses, and process tanks because of their low conductivity and high-strength-to-weight ratio. Other applications include flotation devices, encapsulation, structural and decorative furniture components, and sheathing and roof insulation for buildings.

Integral Skin Foam

Urethane foams that are formed with integral skins ranging from soft and flexible types to impact-absorbing grades and rigid foams used in structural parts. Color can be added, but since the foams yellow on aging, black is most practical for the surface color. If other colors are required, coatings are recommended. The tough, high-density, integral skin is formed against the mold surface, and the low-density core is produced by a blowing agent—usually a fluorocarbon.

Elastomeric foams of this type are used in automotive bumper and fascia systems and, most recently (reinforced with milled glass fibers), in fenders and other exterior body panels. The semirigid types are used in athletic protective gear, in automotive crash-protection areas, horn buttons, sun visors, and armrests. Applications for the rigid structural foams include housings for computer systems, chair shells, furniture drawers, and sports equipment.

Part Fabrication

A low-pressure molding process—reaction injection molding (RIM)—is used almost exclusively to produce urethane parts, some weighing as much as 45.4 kg. In the process, two more highly reactive liquid systems injected with high-pressure impingement mixed into a closed mold at low pressure, where they react to form a finished polymer. Depending on formulation, the polymer can be a rigid, integral skin, microcellular urethane foam with a flexural modulus of over 680 MPa or a soft, flexible elastomer with a flexural modulus as low as 49.06 MPa or a rigid structural foam having a density of 830.4 g/cm³. Cycle time is short; parts can be demolded in less than a minute.

Reinforcement in the form of milled glass fiber, glass flake, or mineral filler increases the stiffness, the thermal properties, and dimensional stability of RIM parts. Maximum glass content in reinforced reaction injection molding (RRIM) is about 25%—a limit determined by the increased viscosity with increasing glass. Natural color of unpigmented RIM urethane parts is tan.

Applications

Reticulated polyester foams are used for explosion suppression. The material protects aircraft fuel tanks from small arms gunfire. Over the years, several technical advances were made to the foam, lowering weight and increasing service life and conductivity (to prevent static buildup).

The material is an open-pore, reticulated polyurethane foam that contains a network of skeletal strands with 98% void space at any pore size. The material functions essentially as a 3D fire screen similar to a safety fire screen over a lighted Bunsen burner.

In a fuel tank, the empty space above the ullage may readily contain an explosive mixture of fuel vapor and air. Since the liquid fuel

P

itself does not explode, a completely filled tank is far less likely to explode than one that is not. The lower the fuel level in the tank, the greater amount of explosive vapor present. When an ignition source is present, the vapor adjacent to the spark ignites rapidly. This ignition, in turn, ignites the vapor around it, creating a chain reaction as the ignition, or flame front, gets larger and moves faster as it propagates through the vapor. The rapid ignition and propagation of the flame results in an ever-growing compression wave in front of it, compressing the unignited vapor, thus adding even greater force to an explosion. This sequence occurs in milliseconds.

This chain reaction is prevented from occurring; instead, vapor ignition is confined to the area immediately around the ignition source. Flame and wave propagation are mitigated by the foam, thus preventing an explosion.

The foam may be easily fabricated into any configuration by conforming to the inside of complex, rigid or flexible, bladder-type fuel tanks. Once installed, the foam can remain in the fuel tank for many years without degradation or loss of physical properties and performance characteristics. They can be readily removed for internal fuel tank maintenance and reinstalled repeatedly.

In the Volkswagen Beetle, polyurethane raw materials protect the finishes of plastic and metal components, both exterior and interior. Polyurethane foam is used inside the doors and instrument panel, and polyurethane raw materials help protect the instrument panel.

Polyvinyl Acetals

Members of the family of vinyl plastics. Polyvinyl acetal is a general name for resins produced from a condensation of polyvinyl alcohol with an aldehyde. There are three main groups: polyvinyl acetal itself, *polyvinyl butyral*, and *polyvinyl formal*. Polyvinyl acetal resins are thermoplastics that can be processed by casting, extruding, molding, and coating, but their main uses are in adhesives, lacquers, coatings, and films.

Polyvinyl Acetate

A thermoplastic material composed of polymers of vinyl acetate in the form of a colorless solid. It is obtainable in the form of granules, solutions, lattices, and pastes and is used extensively in adhesives, for paper and fabric coatings, and in bases for inks and lacquers.

Polyvinyl Acetate Emulsion Adhesive

A latex adhesive in which the polymeric portion comprises polyvinyl acetate, copolymers based mainly on polyvinyl acetate, or a mixture of these and which may contain modifiers and secondary binders to provide specific properties.

Polyvinyl Alcohol

A thermoplastic material composed of polymers of the hypothetical vinyl alcohol. Usually a colorless solid, insoluble in most organic solvents and oils, but soluble in water when the content of hydroxyl groups in the polymer is sufficiently high; the product is normally granular. It is obtained by the partial hydrolysis or by the complete hydrolysis of polyvinyl esters, usually by the complete hydrolysis of polyvinyl acetate. It is mainly used for adhesives and coatings.

Polyvinyl Butyral

A thermoplastic material derived from a polyvinyl ester in which some or all of the acid groups have been replaced by hydroxyl

groups and some or all of these hydroxyl groups have been replaced by butyral groups by reaction with butyraldehyde. It is a colorless, flexible, tough solid used primarily in interlayers for laminated safety glass. See also *polyvinyl acetals*.

Polyvinyl Carbazole

A thermoplastic resin, brown in color, obtained by reacting an acetylene with carbazole. The resin has excellent electrical properties and good heat and chemical resistance. It is used as an impregnant for paper capacitors.

Polyvinyl Chloride Acetate

A thermoplastic material composed of copolymers of vinyl chloride and vinyl acetate. It is a colorless solid with good resistance to water as well as concentrated acids and alkalis. It is obtainable in the form of granules, solutions, and emulsions. Compounded with plasticizers, it yields a flexible material superior to rubber in aging properties. It is widely used for cable and wire coverings, in chemical plants, and in protective garments.

Polyvinyl Chloride (PVC)

Among the vinyl polymers and copolymers, the PVC thermoplastics are the most commercially significant. With various plasticizers, fillers, stabilizers, lubricants, and impact modifiers, PVC is compounded to be flexible or rigid, opaque or transparent, to have high or low modulus, or to have any of a wide spectrum of properties or processing characteristics.

PVC resin can also be chlorinated and it can be alloyed with other polymers such as ABS (acrylonitrile–butadiene–styrene), acrylic, polyurethane, and a nitrile rubber to improve impact resistance, tear strength, resilience, heat-deflection temperature, or processability.

Forms

PVC is a hard, flame-resistant, and chemical-resistant thermoplastic resin. The resin is available in the powder form, as a latex, or in the form of plastisol, PVC resin, pigments, and stabilizers are milled into plasticizers to form a viscous coating material (plastisol) that polymerizes into a tough elastic film when heated. Plastisols are used extensively for coating glass bottles and glass fabrics. The dispersion types of resins are used in flexible molding compounds. Such formulations consist of a vinyl paste resin, a suitable plasticizer such as dioctyl phthalate, and a stabilizer (usually a compound of lead). Flexible molds are widely applied to plaster casting and encapsulation of electronic circuits with epoxy resins.

Processing

PVC compounds are processed by extrusion, injection molding, calendaring, compression molding, and blow molding. PVC coatings are applied by fluidized-bed and electrostatic powder-coating methods. The resins are also used for dip molding and coating, in the form of plastisols and organosol dispersions or water dispersions (latexes). Cellular PVC products are made by introducing gas into the resin during molding or extrusion. Foams can be open or closed cell and can be elastomeric or rigid, depending on plasticizer content.

PVC compounds can be made water white in flexible compounds and very clear in rigid compounds, and they can be pigmented to almost any color.

Properties

With so many property variations attainable by compounding methods, no single compound can be considered typical of PVC. For example, creep rate of rigid compounds is so low and predictable that they can be used to make pressure pipe for water distribution; flexible compounds can be soft enough, yet impermeable, so that they are used for baby pants and for an excellent imitation suede, or they can be transparent, nontoxic, and tough enough to be used for mineral water bottles.

Rigid PVC, sometimes called the “poor man’s engineering plastic,” is a hard, tough material that can be compounded to a wide range of properties. Noteworthy among its properties is low combustibility; it has high resistance to ignition and is self-extinguishing. It also provides good corrosion and stain resistance, thermal and electrical insulation, and weatherability. However, PVC is attacked by aromatic solvents, and ketones, aldehydes, naphthalenes, and some chloride, acetate, and acrylic esters. Some impact modifiers used in rigid PVC reduce chemical resistance. In general, normal-impact grades have better chemical resistance than the high-impact grades.

Most PVC compounds are not recommended for continuous use above 60°C. Chlorination increases heat-deflection temperature, flame retardancy, and density and extends the continuous-use temperature to 80°C–100°C, depending on the amount of chlorination.

Polyvinyl Formal

One of the groups of polyvinyl acetal resins made by the condensation of formaldehyde in the presence of polyvinyl alcohol. It is used mainly in combination with cresylic phenolics, for wire coatings, and for impregnations, but can also be molded, extruded, or cast. It is resistant to greases and oils.

Polyvinylidene Chloride

A thermoplastic material composed of polymers of vinylidene chloride (1,1-dichloroethylene). It is a white powder with a softening temperature at 185°C–200°C (365°F–390°F). The material is also supplied as a copolymer with acrylonitrile or vinyl chloride, giving products that range from the soft, flexible type to the rigid type. Also known as *saran*.

Polyvinylidene Fluoride

This recent member of the fluorocarbon family of plastics is a homopolymer of polyvinylidene fluoride. It is supplied as powders and pellets for molding and extrusion and in solution form for casting. The resin has good tensile and compressive strength and high impact strength.

Polyvinyl Resins

These resins are polymeric materials generally considered to include polymers derived from monomers.

Many of the monomers can be prepared by addition of the appropriate compound to acetylene. For example, vinyl chloride, vinyl fluoride, vinyl acetate, and vinyl methyl ether may be formed by the reactions of acetylene with HCl, HF, CH₃OOH, and CH₃OH, respectively. Processes based on ethylene as a raw material have also become common for the preparation of vinyl chloride and vinyl acetate.

The polyvinyl resins may be characterized as a group of thermoplastics, which, in many cases, are inexpensive and capable of being handled by solution, dispersion, injection-molding, and extrusion

techniques. The properties vary with chemical structure, crystallinity, and molecular weight.

Polyvinyl Acetals

These are relatively soft, water-insoluble thermoplastic products obtained by the reaction of polyvinyl alcohol (PVAL) with aldehydes. Properties depend on the extent to which alcohol groups are reacted. Polyvinyl butyral (PVB) is rubber and tough and is used primarily in plasticized form as the inner layer and binder for safety glass. Polyvinyl formal is the hardest of the group. It is used mainly in adhesive, primer, and wire-coating formulations, especially when blended with a phenolic resin.

PVB is usually obtained by the reaction of butyraldehyde with PVAL. The former can be produced by the same process, but is more conveniently obtained by the reaction of formaldehyde with polyvinyl acetate in acetic acid solution.

Polyvinyl Acetate

Polyvinyl acetate is a leathery, colorless thermoplastic material that softens at relatively low temperatures and that is relatively stable to light and oxygen. The polymers are clear and noncrystalline. The chief applications of polyvinyl acetate are in adhesives and binders for water-based or emulsion paints.

Vinyl acetate is conveniently prepared by the reaction of acetylene with acetic acid.

Polyvinyl Alcohol (PVAL)

PVAL is a tough, whitish polymer that can be formed into strong films, tubes, and fibers that are highly resistant to hydrocarbon solvents. Although PVAL is one of the few water-soluble polymers, it can be rendered insoluble in water by drawing or by the use of cross-linking agents.

Polyvinyl Chloride (PVC)

PVC is a tough, strong thermoplastic material that has an excellent combination of physical and electrical properties. The products are usually characterized as plasticized or rigid types. PVC (and copolymers) is the second most commonly used polyvinyl resin and one of the most versatile plastics.

Polyvinylidene Chloride (PVDC)

PVDC is a tough, horny thermoplastic with properties generally similar to those of PVC. In comparison with the latter, PVDC is softer and less soluble; it softens and decomposes at lower temperatures, crystallizes more readily, and is more resistant to burning.

Because of its relatively low solubility and decomposition temperature, the material is most widely used in the form of copolymers with other vinyl monomers, such as vinyl chloride. The copolymers are employed as packaging film, rigid pipe, and as filaments for upholstery and window screens.

Films of PVDC, and especially the copolymer containing about 15% of vinyl chloride, are resistant to moisture and gases. Also, they can be heat-sealed and, when oriented, have the properties of shrinking on heating. By warming a food product wrapped loosely with a film of the polymer, a skin tight, tough, resistant coating is produced.

By cold-drawing, the degree of crystallinity, strength, and chemical resistance of sheets, filaments, and even piping can be greatly increased.

P

Polyvinyl Ethers

Polyvinyl ethers exist in several forms varying from soft, balsam-like semisolids to tough, rubbery masses, all of which are readily soluble in organic solvents. Polymers of the alkyl vinyl ethers are used in adhesive formulations and a softening or flexibilizing agents for other polymers.

Polyvinyl Fluoride (PVF)

PVF is a tough, partially crystalline thermoplastic material that has a higher softening temperature than PVC. Films and sheets are characterized by high resistance to weathering.

Films are used in industrial and architectural applications. Coatings, for example, on pipe, are resistant to highly corrosive media.

POM

See *polyoxymethylene*.

Pop Riveting

A technique for making riveted lap joints in sheet or other thin material with access from one side only. The tee-shaped hollow rivet carries a pin-headed mandrel through its bore, the mandrel shaft emerging at the head end of the rivet. A hole, of a diameter just sufficient to allow passage of the rivet shank and mandrel head, is drilled through the pair of sheets. The shank of the rivet, with the mandrel head projecting beyond it, is inserted through the hole and the mandrel is then drawn back so that its head expands the projecting shaft bore. The rivet firmly nips the sheets before the mandrel breaks leaving its head on the foreface of the sheets.

Pop-Off

Loss of small portions of a porcelain enamel coating. The usual cause is outgassing of hydrogen or other gases from the basis metal during firing, but pop-off may also occur because of oxide particles or other debris on the surface of the basis metal. Usually, the pits are minute and cone shaped, but when pop-off is the result of severe *fish scale*, the pits may be much larger and irregular.

Population

In statistics, a generic term denoting any finite or infinite collection of individual samples or data points in the broadest concept; an aggregate determined by some property that distinguishes samples that do and do not belong.

Porcelain

Porcelains and stoneware are highly vitrified ceramics that are widely used in chemical and electrical products. Electrical porcelains, which are basically classified clay-type ceramics, are conventionally divided into low- and high-voltage types. The high-voltage grades are suitable for voltages of 500 and higher and are capable of withstanding extremes of climatic conditions. Chemical porcelains and stoneware are produced from blends of clay, quartz, feldspar, kaolin, and certain other materials. Porcelain is more vitrified than stoneware and is white in color. A hard glaze is generally applied. Stoneware can be classified into two types: a dense, vitrified body

for use with corrosive liquids and a less dense body for use in contact with corrosive fumes. Chemical stoneware may range from 30% to 70% clay, 5% to 25% feldspar, and 30% to 60% silica. The vitrified and glazed product will have a tensile strength up to 16 MPa and a compressive strength of 551 MPa. Industrial stoneware is made from specially selected or blended clays to give desired properties.

Both chemical porcelains and stoneware resist all acids except hydrofluoric. Strong, hot, caustic alkalies mildly attack the surface. These ceramics generally show low thermal shock resistance and tensile strength. Their universal chemical resistance explains their wide use in the chemical and processing industries for tanks, reactor chambers, condensers, pipes, cooling coils, fittings, pumps, ducks, blenders, filters, and so on.

Ceratherm is an acid-resistant and heat-shock-resistant ceramic with a base of high-alumina clay. It is strong and nonporous and is used for pump and chemical-equipment linings.

Properties

Porcelain is distinguished from other fine ceramic ware, such as china, by the fact that the firing of the unglazed ware (the bisque firing) is done at a lower temperature (1000°C–1200°C) than the final or gloss firing, which may be as high as 1500°C. In other words, the ware reaches its final state of maturity at the maturing temperature of the glaze.

The white color is obtained by using very pure white-firing kaolin or china clay and other pure materials, the low absorption results from the high firing temperature, and the translucency results from the glass phase.

This term is frequently used as a synonym for *china*.

Porcelain Enamels and Ceramic Coatings

Earlier definitions of ceramic materials usually stressed their mineral origin and the need for heat to convert them into useful form. As a consequence, only porcelain enamels and glazes were recognized as ceramic coatings until recently when the principles of phase relations, bonding mechanisms, and crystal structure were applied to ceramic materials and to coatings made from them. In consequence, ceramic materials can now be most safely defined as solid substances that are neither metallic nor organic in nature, a definition that is somewhat more inclusive than older ones, but more accurately reflects modern scientific usage.

Most ceramics are metal oxides or mixtures and solutions of such oxides. Certain ceramic materials, however, contain little or no oxygen. As a whole, ceramic materials are harder, more inert, and more brittle than organic or metallic substances. Most ceramic coatings are employed to exploit the first two properties while minimizing the third.

Low-Temperature Coatings

The outstanding resistance to corrosion of certain metals, notably aluminum and chromium, is attributable to the remarkable adherence of their oxide films. Aluminum does not corrode because its oxidation product, unlike that of iron, is a highly protective coating. It was once believed that some mysterious kinship between a metal and its own oxide was needed for this protection, but recent knowledge relating to the structure of metals and metal oxides has enabled metallurgists to develop alloys that form even more stable and adherent films. Methods for thickening or stabilizing these oxide coatings by heat treatment, electrolysis, or chemical reaction are widely accepted.

The presence of such coatings on metals and alloys strongly influences such properties as their emission and absorption of

radiation, frictional and wetting characteristics, and electrical and electrochemical properties.

Usually, ceramic coatings contain compounds of metals other than the substrate. Most of these are oxides, which are amorphous or cryptocrystalline in nature. They can be divided into two groups: chemical reactants (in which a new compound or complex is formed) and inorganic colloids.

Chemical Reactants

These coatings usually involve a chemical modification of the natural metal oxide into a coating that is stabler or denser. This classification includes the treatment of aluminum, tin, and zinc, with chromates, electrolytic “anodizing,” the treatment of iron with soluble phosphates, etc. The films that are formed are more inert to most chemicals than normal oxide films, and the process is termed “passivation.”

Inorganic Colloids

Colloidal particles are sufficiently small so that their surface energy is sufficient for bonding. These particles can be made into colloidal suspensions called “slurries” or “slips.” They contain natural colloids such as hydrophilic clays, or finely ground materials of a fibrous or platelike nature such as asbestos, mica, graphite, potassium titanate, alumina monohydrate, zirconia hydrate, or molybdenum sulfide.

Some inorganic colloids are so finely dispersed as to be true sols. “Water glass” is a familiar example of the colloidal sol; depending on its sodium content, alkalinity, and dilution, it may be a thin fluid, a sticky, viscous liquid, or a translucent semisolid. Newer aqueous sols include other alkali silicates, aluminum acid hydrates and phosphates, alkyl titanates and silicates, and lime hydrate.

These coatings are usually processed by drying or flocculation. The dry film and substrate are usually heated sufficiently to drive off all traces of moisture and irreversibly “set” the coating for its final use, as for lubricants, thermionic emitters, and fluorescent lamp coatings. The relatively weak bonding power of these dried films can be used to hold them in place for further heating; this is the basis of “wet process” porcelain enameling.

Moderate Temperature Processes

In the temperature range between 538°C and 1093°C, most silicate glasses melt. In this range, the fusion of a vitreous powder (usually called a frit) or the formation of a glass from its component materials is then used as the basis for porcelain enameling and glazing processes.

Glazes differ from enamels principally in the substrates on which they are applied. When the substrate is metallic, the vitreous coating is called an enamel; when applied to ceramic bodies such as porcelain, china, terra cotta, pottery, and electrical ceramics, the coating is termed a glaze. Since these coatings are vitreous, they may be transparent, but most enamels and many glazes contain finely divided crystalline materials that color them and make them more or less opaque.

Enamels are used primarily to provide resistance to corrosion, heat, and/or abrasion and wear; they are frequently employed for their attractive appearance as well.

Vitreous enamels cannot easily be classified; a typical enameling slip may contain 10 or more ingredients, including those that are glassy or form a vitreous network (feldspars, frits, borax, and other mineral sources of silicates, phosphates, and borates). The modifiers usually consist of alkali and alkaline earth compounds or lead. They also contain fluxing agents, opacifiers, suspending agents, and clays,

as well as refractory oxides intended to dissolve in the melting glass and increase its viscosity. The oxides or other compounds of cobalt, nickel, manganese, arsenic, or antimony may be included to promote adhesion between glass and metal.

Most porcelain enamels consist of two or more layers of glass, separately applied and fused. The first layer is called the ground coat or base coat; its purpose is to attach firmly to the metal substrate and prevent undesirable interactions between substrate and enamel or the evolution of gas from the metal. It is in the ground coat that the adherence-promoting additives are used, and it is these additives that produce the blue, brown, or black color of most ground coats. Where light colors are not required (range parts, heat-resisting coatings, and certain abrasion-resistant applications), a ground coat may suffice over the base metal.

Although “cover coat” may be required to resist chemical attack, abrasion, impact, heat, or weathering, enamels are most commonly used to provide a durable and attractive finish for steelhead ferrous alloys. Most of these are white, hence the name “porcelain” enamels. Earlier enamels contain antimony or zircon to provide opacity and whiteness, but zirconium oxide and titanium oxide are now most frequently used. The latter not only provides superior opacity but usually improves acid resistant as well. As a consequence, titanium-bearing enamels may be applied in a single coating, not only over a suitable base coat but also directly upon special steels. Such enamels can now be fused at less than 760°C to titanium-bearing steels, to steels precoated with a thin nickel film, or to steels pretreated with iron phosphate.

On cast iron, enamels are used for range parts and a high-grade sanitary ware. Certain chemical ware (tanks, pumps, etc.) are also made with cast iron. The rigidity and good acoustical damping of cast iron, together with its resistance to distortion by heat, permits heavier layers of the protective glass to be used than are possible on steel or enameling iron.

Special enamels have been developed for the chemical industry and hot water tanks. Such equipment is frequently called “glass lined,” and can contain all acids except hydrofluoric and hot phosphoric, moderately alkaline solutions up to their boiling point, and water under pressures up to 3500 MPa.

Enamels are not limited to use on ferrous substrates; the earliest decorative enamels were used on precious metals and copper hardware and jewelry. Enamels have recently been developed suitable for aluminum. Such enamels can be fired at temperatures well below 538°C. Although not so hard or corrosion resistant as sheet-steel enamels, these aluminum enamels provide attractive and durable finishes for sheet, extrusions, and castings.

Although most enamels are applied to the substrate by a wet-process technique, some coatings may be applied by dusting or sieving the powdered composition directly upon the heated surface. This “dry process” is principally used with chemical ware and cast iron sanitary ware.

The mechanical properties of enamels are strongly influenced by the composition, thickness, and geometry of the substrate as well as by the kind, thickness, method of application, and firing conditions of the enamel layer or layers. In general, thin enamel coatings are best able to resist thermal and mechanical shock and stress. Very thin (1–4 mils thick) coatings on steel or aluminum may even be bent, punched, sheared, or drilled without damage. Thicker coatings are usually required for ordinary applications (in appliances, curtain walls or structural panels, and signs); the thickness of the glassy layers is usually between 3 and 20 mils. For cast iron sanitary ware, the vitreous coating may be 40 mils thick or more, and some chemical tanks employ 6.4 mm of protective glass.

For maximum resistance to chipping, the enamel must be supported by a hard, relatively thick substrate. Where the enamel's

article must resist bending or twisting, thinner and more ductile substrates are indicated.

The selection of metal for porcelain enamel and its preparation strongly influences the properties of the composite. "Enameling irons" are essentially very low carbon, basic open-hearth, rimmed steels. Regular SAE (Society of Auto Engineers) and AISI (American Iron and Steel Institute) low-carbon steels can seldom be perfectly enameled especially when hot-rolled. Premium enameling stock may contain titanium sufficient to further lower the available carbon content and improve resistance to warping or sagging.

For thicker substrates, a basic open-hearth plate steel of flange quality may be used. Higher impurity levels, however, may require that the enamel be fired in an inert atmosphere to eliminate "boiling" defects. In some cases, aluminized steel can be used in moderately oxidizing furnace atmospheres.

Cast steel and cast iron can be enameled acceptably; carbon is oxidized from the surface during the relatively long firing period needed to fuse and consolidate the ground coat. Purity of the metal is not so stringent a requirement for cast iron as for steel.

Surface treatment of the metal usually requires the removal of all scale and dirt (this may require sandblasting for heavy-gauge stock) followed by a light pickling for ultimate control of the oxide layer thickness. For some metals and cast irons, sandblasting or grit blasting alone may be sufficient pretreatment. Special enamels may require phosphate bath treatment or the deposition of a nickel-, copper-, or aluminum-base coating over the metal.

Metals to be enameled should be reasonably strain-free. Burrs, sharp edges, or small external radii and large variations in substrate thickness should be avoided. Welds must be sound and metallurgically similar to the parent area.

Refractory Enamels and Glazes

Because the fused porcelain enamel cools with its substrate, it is important that the total contraction that occurs during cooling be approximately equal in both metal and glass. If the metal contracts more than the enamel, the latter will be forced into compression and may shatter or chip easily; if the enamel contracts more than the metal, it will crack or craze.

Among the silicate glasses, the most refractory generally have a low thermal expansion coefficient, and they must therefore be used on metals that have low expansion. Most of the refractory enamels contain finely powdered silica and chromium oxide, which dissolve in the glass on fusion, further lowering expansion. In consequence, such enamels are largely restricted to refractory substrate metals such as certain stainless steels and nickel and chromium alloys. The service temperature of enamel-coated stainless steel and nickel alloys is about 954°C in aircraft engine exhaust manifolds, turbosupercharger linings, jet engine combustors, and commercial burners.

Thin, electrically conductive ceramic coatings can be used as resistance heaters on aircraft windshields and the like. Most of these consist of a mixture of the oxides and suboxides of tin with traces of bismuth, antimony, cadmium, or arsenic. They are applied by heating the glass to a dull red heat and spraying it with a fusible tin halide under slightly reducing conditions. As it cools in air, the tin halide decomposes into the conductive complex. When sufficiently thin, these coatings are quite transparent.

High-Temperature Coatings

To attach a ceramic coating to any substrate by enameling, both substrate and glass must be heated to the fusion temperature of the

glass. However, fusion methods have not been successful for the more refractory materials. Because most refractory ceramic coatings are amorphous or crystalline in nature, they have to be applied by relatively novel techniques.

Although most ceramic materials are refractory, some of them can be vaporized in an electric arc or hot vacuum. Thin coatings of amorphous silica can be applied readily to relatively cool substrates by vaporizing metallic silicon or silicon halides in the presence of small quantities of oxygen. Apparently, the transfer is accomplished largely as silicon monoxide, which recombines with oxygen on cooling. The process is used to obtain thin, protective, optically transparent films on lenses, certain electrical components, and metal reflectors.

Other ceramic coatings may be produced by vaporizing one or more components of the coating. In this way, coatings of their respective carbides of silicon, boron, aluminum, and chromium can be deposited on graphite, silicon nitride can be formed on metallic silicon, and silicide coatings can be deposited on metals such as tungsten and molybdenum. These processes are necessarily expensive and are poorly adaptable to large specimens or complex shapes.

Flame or Arc Spraying

Many metallic oxides and interstitial compounds can be heated to or above their melting temperatures with a chemical flame or electrical arc. The coatings obtained by directing a spray of nearly molten ceramic particles toward an otherwise unheated substrate are interesting and useful for a variety of purposes. Most of the processes are proprietary and differ chiefly in the form in which material is fed into the heat source.

The coatings obtained in this way may be quite porous, or they may approach the theoretical density of the material being sprayed. Since the substrate need not be heated, the need for a close match of thermal expansion is less important than with vitreous coatings. The porous coatings are surprisingly immune to thermal and mechanical shock, but confer little chemical protection.

Substrates must usually be roughened before application of these coatings, but heat-resistant glasses, glazes, and some porcelain enamels make excellent substrates. Adherence seems to be largely mechanical, and the adherence tests used for porcelain enamels are not applicable to these coatings. No standards for testing or performance have yet been established.

Coatings obtained by flame spraying may consist of pure ceramic materials, metals, and some organic polymers; a modification of flame spraying can be used to produce pyrolytic graphitic coatings of high density and resistance to hot gas erosion. Mixtures of ceramic and metal powders may be used to produce cermet coatings or even graded coatings, and unusual electrical, magnetic, and dielectric properties can be obtained with such mixtures or with multilayer application.

Because each particle is suddenly and individually chilled, the structure of flame-sprayed ceramics may be unlike those of the bulk materials. Nonstoichiometry is common, and the stresses in the coating and between the coating and substrate are complex. Nevertheless, certain flame-sprayed and arc plasma-sprayed coatings have already found acceptance in missile technology and metalworking in foundry applications and for heat- or wear-resistant coatings on metallic, ceramic, and polymer substrates.

Pore

(1) Voids in a material. Usually the term implies voids that individually are of small size relative to the section and particularly those resulting from gas entrapment during solidification. In the case of a highly porous materials, the porosity is often reported as a percentage

by volume. (2) A small opening, void, interstice, or channel within a consolidated solid mass or agglomerate, usually larger than atomic or molecular dimensions. (3) A minute cavity in a powder-metallurgy compact, sometimes added intentionally. See also *porous P/M parts*. (4) A minute perforation in an electroplated coating.

Pore Area

The effective surface porosity of a sintered powder-metallurgy compact to determine the permeability to a test fluid.

Pore Channels

The connections between pores in a sintered body.

Pore Formation

The natural formation of pores during compaction and/or sintering. See also *pore-forming material*.

Pore Size

Width of a pore in a compacted and/or sintered metal powder or within a particle.

Pore Size Distribution

Indicates the volume fractions of different pore size categories in a sintered body, which are determined metallographically.

Pore Size Range

The limits between which a variation in pore size and a sintered body is allowed.

Pore Structure

Pattern of pores in a solid body indicating such characteristics as pore shape, *pore size*, and *pore size distribution*.

Pore-Forming Material

A substance included in a metal powder mixture that volatilizes during sintering and thereby produces a desired kind of porosity in a finished compact.

Porosimeter

A test apparatus to measure the interconnected porosity in a sintered compact by means of determining its permeability through use of a test fluid such as mercury, which either partially or completely fills the open pores.

Porosity

(1) Fine holes or pores within a solid; the amount of these pores is expressed as a percentage of the total volume of the solid. (2) Cavity-type discontinuities in weldments formed by gas entrapment during solidification. (3) Trapped air or shrinkage in a casting. A characteristic of being porous, with voids or pores resulting from trapped air or shrinkage in a casting. See also *gas porosity* and *pinhole porosity*.

Porous Bearing

A bearing made from porous material such as compressed and sintered metal powder. The pores may act as reservoirs or passages for supplying fluid lubricant, or the bearing may be impregnated with solid lubricant. See also *self-lubricating bearing*.

Porous Metals

These are metals with uniformly controlled pore sizes, in the form of sheets, tubes, and shapes, used for filtering liquids and gases. They are commonly made by powder metallurgy, and the pore size and density are controlled by the particle size and the pressure used. Stainless steel, nickel, bronze, silver, and other metal powders are used, depending on the corrosion resistance required of the filter. Pore sizes can be as small as 0.2 μm , but the most generally used filters have pores of 4, 8, 12, and 25 μm . Pore sizes have a uniformity within 10%. The density range is from 40% to 50% of the theoretical density of the metal. Standard filter sheet is 0.76–1.52 cm, but thinner sheets are available. Sheet as thin as 0.010 cm, and with void fractions as high as 90%, have been made for fuel cells in catalytic reactors. Porous steel is made from 18-8 stainless steel, with pore openings from 20 to 65 μm . The fine-pore sheet has a minimum tensile strength of 69 MPa, and the coarse sheet has a strength of 48 MPa. Felted metal is porous sheet made by felting metal fibers, pressing and sintering. It gives a high-strength-to-porosity ratio, and the porosity can be controlled over a wide range. In this type of porous metal, the pores may be from 0.003 to 0.038 cm in diameter and of any metal to suit the filtering conditions. A felted fiber filter of 430 stainless steel with 25% porosity has a tensile strength of 172 MPa.

Porous Molds

Molds for forming plastics that are made up of bonded or fused aggregate (powdered metal, coarse pellets, and so forth) such that the resulting mass contains numerous open interstices of regular or irregular size allowing either air or liquids to pass through the mass of the mold.

Porous Powder-Metallurgy (P/M) Parts

P/M components that are characterized by *interconnected porosity*. Primarily, application areas for porous P/M parts are filters, damping devices, storage reservoirs for liquids (including self-lubricating bearing), and battery elements. Bronzes, stainless steels, nickel-base alloys, titanium, and aluminum are used in P/M porous metal applications.

Porous Region (Ceramics)

A 3D zone of porosity or microporosity of higher concentration than is normally found in the ceramic matrix.

Porous Seam (Ceramics)

A 2D area of porosity or microporosity of higher concentration than is normally found in the ceramic matrix.

Port

The opening through which molten metal enters the injection cylinder of a *die-casting* plunger machine or is ladled into the injection

P

cylinder of a cold chamber machine. See also *cold chamber machine* and *plunger*.

Portable Hardness Testing

Techniques and equipment for hardness testing on site rather than using large unwieldy laboratory equipment. With due care, the quality of the results is adequate for most purposes.

Porthole Die

A multiple-section extrusion die capable of producing tubing or intricate hollow shapes without the use of a separate mandrel. Metal is extruded in separate streams through holes in each section and is rewelded by extrusion pressure before it leaves the die. Compare with *bridge die*. See also *tube making*.

Positioned Weld

A weld made in a joint that has been oriented to facilitate making the weld.

Positive Distortion

In an optical microscope, the distortion in the image that results when the magnification in the center of the field is less than that at the edge of the field. Also termed pincushion distortion. See also *negative distortion*.

Positive eyepiece

In an optical microscope, an eyepiece in which the real image of the object is formed below the lower lens elements of the eyepiece. See also *eyepiece*.

Positive Ion

An ion, which may be an atom, molecule, or radical, which has lost one or more electrons and hence carries a positive charge.

Positive mold

A mold for forming plastics designed to trap all the molding material when it closes.

Positive Rake

Describes a tooth face in rotation whose cutting edge leads the surface of the tooth face. See also *face mill*.

Positive replica

A replica whose contours correspond directly to the surface being replicated. Contrast with *negative replica*.

Positive-Contact Bushing

A bushing, the inside diameter of which has direct contact with the outside diameter of a shaft or sleeve. Radial or axial clearances are provided in the hole.

Positive-Contact Seal

A seal, the primary function of which is achieved by one surface mating with another. Examples include lip, circumferential, and face-type seals. See also *face seal*.

Positron

Subatomic particles having the same mass as an electron but a positive charge. See *atom*.

Post (Weld)-Heat Treatment

Any process of heating following welding or some other process. Such heating induces stress relief, softening of hardened zones, diffusion of hydrogen, etc. This term usually refers to circumstances where the weldment is allowed to cool fully before being reheated perhaps in some special facility away from the welding site; compare with *postheating*.

Postcure (Adhesives)

A treatment (normally involving heat) applied to an adhesive assembly following the initial cure, to modify specific properties. To expose an adhesive assembly to an additional cure, following the initial cure, for the purpose of modifying specific properties.

Postcure (Plastics)

Additional elevated-temperature cure of a plastic, usually without pressure, to improve final properties and/or complete the cure or decrease the percentage of volatiles in the compound. In certain resins, complete cure and ultimate mechanical properties are attached only by exposure of the cured resin to higher temperatures than those of curing. See also *cure*.

Postforming

The forming, bending, or shaping of fully cured, C-staged thermoset laminates that have been heated to make them flexible. Upon cooling, the formed laminate retains the contours and shape of the mold over which it has been formed. See also *C-stage*.

Postheat Current

In resistance welding, the current through the welding circuit during *postheat time*.

Postheat Time

In resistance welding, the time from the end of weld heat time to the end of weld time. See also *postheat current*.

Postheating

Heating weldments immediately after welding, for tempering, for stress relieving, or for providing a controlled rate of cooling to prevent formation of a hard or brittle structure, hydrogen diffusion, etc. If the welded component is allowed to cool before being reheated, the term post (weld)-heat treatment is more appropriate.

Pot (Metals)

(1) A vessel for holding molten metal. (2) The electrolytic reduction cell used to make such metals as aluminum from a fused electrolyte.

Pot (Plastics)

To embed a component or assembly in liquid resin, using a shell, can, or case that remains an integral part of the product after the resin is cured.

Pot Annealing

Same as *box annealing*.

Pot Die Forming

Forming products from sheet or plate through the use of a hollow die and internal pressure that causes the preformed workpiece to assume the contour of the die.

Pot Life

The length of time that a catalyzed thermosetting resin system retains a viscosity low enough to be used in processing. Also called working life.

Potash

Also called *pearl ash*. A white, alkaline, granular powder, which is a potassium carbonate, K_2CO_3 , used in soft soaps, for wool washing, and in glass manufacture. It is produced from natural deposits and also produced from wood and plant ashes. The U.S. production is largely from potash salts of New Mexico, from the brines of Searles Lake, California, and from solar evaporation in Utah, and usually contains iron, clay, and salt as impurities. *Kalium* is a high-purity grade that results from an evaporation-crystallization step; it has about 62.4% K_2O and less than 1% salt. The material is a free-flowing, white powder of 91%–94% K_2CO_3 or is the hydrate at 84% or calcined at 99% purity. The specific gravity of potash is 2.33 and melting point 1668°F (909°C). The sylvite ore mined at Carlsbad, New Mexico, contains KCl and NaCl. It is electrically refined to 99.95% KCl and is used to produce caustic potash. Electrolysis of the chloride solution yields caustic potash.

Potassium Alloys and Compounds

An elementary metal, symbol K, and atomic weight 39.1, potassium is also known as kalium. It is silvery white in color, but it oxidizes rapidly in the air and must be kept submerged in ether or kerosene.

It stands in the middle of the alkali metal family, below sodium and above rubidium, in group II of the periodic table of the elements. It is a lightweight, soft, low-melting reactive metal. It is very similar to sodium in its behavior and its metallic form, and its uses are limited by the availability of low-cost sodium in large volume.

Physical Properties and Alloys

Potassium has a low melting point of 63°C and a boiling point of 756°C. The specific gravity is 0.855 at 20°C. It is soluble in alcohol and in acids. It decomposes water with great violence. Potassium is obtained by the electrolysis of potassium chloride. Potassium metal is used in combination with sodium as a heat-exchange fluid in atomic reactors and high-temperature processing equipment.

A potassium–sodium alloy contains 78% potassium and 22% sodium. It has a melting point of –11°C and a boiling point of 756°C and is a silvery mobile liquid. Cesium–potassium–sodium alloys are called BZ alloys. Potassium hydride is used for the photosensitive deposit on the cathode of some photoelectric cells. It is extremely sensitive and will emit electrons under a flash so weak and so rapid as to be imperceptible to the eye. Potassium diphosphate, KH_2PO_4 , a colorless, crystalline, or white powder soluble in water, is used as a lubricant for wool fibers to replace olive oil in spinning wool.

It has the advantages that it does not become rancid like oil and can be removed without scouring. Potassium, like sodium, has a broad range of use in its compounds, giving strong bonds. Metallurgically, it is listed as having a body-centered cubic structure, but the atoms arrange themselves in pairs in the metal as K_2 , and the structure is cryptocrystalline.

Chemical Properties

Potassium is even more reactive than sodium. It reacts vigorously with the oxygen in the air to form the monoxide, K_2O , and the peroxide, K_2O_2 . In the presence of excess oxygen, it readily forms the superoxide, KO_2 (formerly believed to be K_2O_4).

Potassium does not react with nitrogen to form a nitride, even at elevated temperatures. With hydrogen, potassium reacts slowly at 200°C and rapidly at 350°C–400°C. It forms the least stable hydride of all the alkali metals.

Principal Compounds

Potassium chloride, KCl, is the most important potassium compound. It is not the only form in which potassium is often found in nature, but it is the form in which potash is used as a fertilizer.

Potassium hydroxide, KOH, is also known as caustic potash. It is usually made by the electrolysis of aqueous solutions of potassium chloride.

Potassium carbonate, K_2CO_3 , is made from potassium hydroxide and carbon dioxide. It cannot be made by the Solvay process used for sodium carbonate, because potassium bicarbonate is too soluble in ammonium chloride solution.

Potassium nitrate, KNO_3 , is made from fractional crystallization of an aqueous solution containing sodium nitrate and potassium chloride.

Handling

Handling of potassium metal is much the same as that of sodium metal, with two major exceptions. First, the formation of the superoxide, KO_2 , causes difficulties because it can react vigorously with hydrocarbons and other organic matter. Second, potassium is generally more reactive than sodium. Potassium forms an explosive carbonyl with carbon monoxide, and the metal deteriorates in contact with bromine. Usually sodium, potassium, and sodium–potassium (NaK) alloys are considered to be in the same general class of reactivity, allowing for the chemical differences outlined previously and for the liquid (and hence more reactive) nature of the NaK alloys over a wide range of composition.

Uses

Potassium chloride finds its main use in fertilizer mixtures. It also serves as the raw material for the manufacture of other potassium compounds.

Potassium hydroxide is used in the manufacture of liquid soaps, and potassium carbonate in making soft soaps.

Potassium carbonate is also an important raw material for the glass industry.

P

Potassium nitrate is used in matches, and pyrotechnics, and in similar items that require an oxidizing agent.

Biological Activity

The recognition of potassium ions by biological molecules is optimal when there is a good match between the cavity size provided by the host molecule and the ionic diameter of the potassium ion; other factors, such as the water structure surrounding the potassium ion and the number and nature of donor atoms in the host molecule, may, however, be important. Novel physical methods, such as nuclear magnetic resonance spectroscopy based on the ^{39}K isotope, are being used to help achieve an improved understanding of potassium ion transport in biological systems.

Potassium deficiency may occur in several conditions including malnutrition and excessive vomiting or diarrhea and in patients undergoing dialysis; supplementation with potassium salts is sometimes required. Although toxicity caused by therapeutic doses of potassium is rare, it may lead to cardiac arrest if left untreated; potassium supplementation should be administered with caution to patients suffering from cardiovascular diseases or those with impaired renal function.

Potassium Compounds

Potash

See *potash* earlier.

The compound K_2O is very soluble in water and other solvents. The most important original source of commercial potash is natural potassium salts. These are prepared as potassium nitrate and potassium carbonate for use in ceramics, but most of the potash is automatically introduced into batches in feld-soda glass; this is especially true with the use of manganese, nickel oxide, and selenium. In the potash glasses, much less cobalt oxide is required in connection with manganese to secure a good neutral tint for crystal glass. Similarly, nickel is a suitable decolorizer for glasses high in potash, whereas its effect in the soda glasses is decidedly ugly.

The alkali content of commercial glasses runs about 15% in window glass, 15%–17% and container glass, and 20% in thin blown glass. Most of the alkali is soda, and while a higher potash content is often desirable, its greater cost limits its wider application. The growth of the American potash industry may allow a price reduction that will make this material more available to glass manufacturers, who now limit its general use to the more expensive glass products.

In optical glass, a ratio of 7 parts potash to 3 parts soda gives good durability and color to a number of commercial compositions, in which the total potash content of the glass may vary from 7% to 16% for some crowned types. It probably is not possible to derive a potash–soda ratio suitable for all optical glasses. Some high-lead glasses, for example, contain no soda at all, yet show high durability. The discoloring effect of ferrous iron is much less noticeable in a potash–soda optical glass than in a high-soda glass.

It has been found that glasses containing both Na_2O and K_2O give lower thermal conduction than either alone; the minimum conductivity is obtained with a potash–soda ratio of 4:1. This factor is becoming increasingly important in view of developments in fiberglass.

The behavior of colorants and colored glass is often superior in potash glass to that in spar.

In enamels, the alkali content averages 10% in sheet ground coats, 20% in cover coats, 15% in cast iron enamels, and as much

as 36% in jewelry enamels. In the last type, all the alkali is potash, which is believed to increase brilliance and luster, but in other enamels, all or most of the potash is merely accessory to alumina in the addition of feldspar. The same may be said for the potash content of glazes. As a flux and glazes, potash is only about 85% as active as soda. If present in excess, K_2O may cause peeling and crazing if the other constituents are not in suitable proportions. Potash is reported not as conductive as soda to the formation of crystals and crystalline glazes.

Potash in the hydroxide or carbonate form is an important defloculating agent. It is used at ordinary temperatures to prepare casting slips, glazed slips, and engobes, to purify clay, to reduce the plasticity of excessively plastic clays, and to neutralize any acid present.

Potassium Carbonate

In glass manufacture, potassium carbonate is supplied in both calcined and hydrated form. The product sold to the glass industry is easy to handle as it is of granular particle form and has entirely eliminated the dusty material, formally supplied from abroad, with its irritating handling problems.

The present domestic materials are supplied with very low chloride and sulfate content and are entirely suitable for all types of glass production. Although the viscosity of the potash glasses is high, thus making them somewhat difficult to work, the viscosity is easily remedied by introducing lead oxide. Hence, the combination of potash and lead oxide leads to the production of a glass that lends itself well to handworking.

This combination possesses a long working range. All of the potash glasses, which from their nature must be melted in closed pots, exert a different sort of corrosive action on the clay wall from that exhibited by soda glasses.

The corrosion by soda glass proceeds quite smoothly, but the potash glasses produce a honeycombing or pitting effect, and the thin partitions between these pits finally reduced to small pinnacles, float out into the glass, forming stones. It seems to be an almost unavoidable characteristic of the potash-lead glasses to produce a great deal of stony ware.

In its influence on the physical properties of glass, potash does not differ greatly from soda. Compared with soda in equal weight percentages, potash seems to confer a little more density, less hardness, and less tenacity. The two are by far the most expansible oxides in glass.

In glazes, potassium carbonate appears as an ingredient when it is desirable to modify the effect of a colorant such as copper oxide, which may be brought through tints of green toward yellow.

When potassium carbonate is used in glazes in combination with sodium oxide, lead oxide, or calcium oxide, the potassium oxide derivative cannot exceed 0.15 equivalent without affecting the color.

When potassium carbonate is used in colored glazes, it is advisable to frit about 90% of the clay, but none of the color.

In enamels, potassium carbonate tends to produce high luster, but it decreases strength and elasticity, making the enamel soft.

In general, enamels containing potassium are more readily fusible than those with sodium. Potassium carbonate has largely been replaced in enamels, however, by sodium carbonate, due to the difference in price, except in occasional cases where it is used to alter colors.

Potassium Chlorate

Also known as chlorate of potash and potassium oxy muriate, this is a white crystalline powder, of lustrous crystalline substance, of the

composition KClO_3 , employed in explosives, chiefly as a source of oxygen. It is also used as an oxidizing agent in the chemical industry, as a cardiac stimulant in medicine, and in toothpaste. It melts at 357°C and decomposes at 400°C with the rapid evolution of oxygen. It is odorless but has a slightly bitter saline taste. The specific gravity is 2.337. It is not hygroscopic, but is soluble in water. It imparts a violet color to the flame in pyrotechnic compositions.

Potassium Chloride

Potassium chloride is a colorless or white crystalline compound of the composition KCl , used for molten salt baths for the heat treatment of steels. The specific gravity is 1.987. A bath composed of three parts potassium chloride and two parts barium chloride is used for hardening carbon steel drills and other tools. Steel tools heated in this bath and quenched in a 3% sulfuric acid solution have a very bright surface. A common bath is made up of potassium chloride and common salt and can be used in high temperatures up to 900°C .

Potassium chloride is used in the porcelain enamel industry as a setting-up agent in titanium cover coats. In general, the quantities of potassium chloride, when used as an electrolyte, will be approximately the same as sodium nitrite, which it replaces. However, KCl does not aid tearing resistance as does nitrite. The main advantage in using potassium chloride is the freedom from yellowing or creaming when used in a blue-white enamel. Potassium chloride may exert an adverse affect on the gloss and may cause a slight decrease in the acid-resisting properties of the enamel, although the latter effect is somewhat debatable.

Potassium Cyanide

A white amorphous or crystalline solid of the composition KCN , potassium cyanide is employed for carburizing steel for case hardening and for electroplating. The specific gravity is 1.52, and it melts at about 843°C . It is soluble in water and is extremely poisonous, giving off the deadly hydrocyanic acid gas. For cyaniding steel, the latter is immersed in a bath of molten cyanide and then quenched in water, or the cyanide is rubbed on the red-hot steel.

Commercial potassium cyanide is likely to contain a proportion of sodium cyanide. Potassium ferrocyanide or yellow prussiate of potash can also be used for case-hardening steel. Nitrogen as well as carbon enters the steel to form the hard case. Potassium ferricyanide, or red prussiate of potash, is a bright-red granular powder used in photographic reducing solutions, in etching solutions, in blueprint paper, and in silvering mirrors. *Redsol* crystal is the name of this chemical uses as a reducer and mild oxidizing agent or toner for photography. Potassium cyanate, KCNO , is a white crystalline solid used for the production of organic chemicals and drugs. It melts at 310°C . The potassium silver cyanide used for silver plating comes in white, water-soluble crystals, known as *Sel-Rex*. Potassium gold cyanide has a similar function in gold plating. *Platina* comes as colorless tablets that are soluble in both water and alcohol.

Potassium Dichromate

This material, $\text{K}_2\text{Cr}_2\text{O}_7$, decomposes at 500°C . Bright yellowish-red crystals that are soluble and poisonous. Sometimes, potassium chromate and dichromate are utilized in ceramics as coloring agents.

Potassium dichromate is used in glass for aventurine effects. It is said that 20–21 parts to 100 parts sand will give a chrome aventurine. This glass is characterized by glittering metallic scales of chromium oxide. Potassium dichromate is also used in glass to give a green color. However, it has been shown that it may cause considerable

trouble by formation of black, chrome corundum crystals in the glass. Air-floated chromite is suggested to avoid this problem.

Potassium dichromate is used in glazes to produce chrome-tin pinks, low-fire reds, greens, and purplish-red colors.

Potassium Nitrate

Potassium nitrate is also called niter and saltpeter, although these usually referred to the native mineral. A substance of the composition KNO_3 , it is used in explosives, for bluing steel, and in fertilizers. A mixture of potassium nitrate and sodium nitrate is used for steel-tempering baths. The mixture melts at 250°C . Potassium nitrate is made by the action of potassium chloride on sodium nitrate. It occurs in colorless prismatic crystals or as a crystalline white powder. It has a sharp saline taste and is soluble in water. The specific gravity is 2.1 and the melting point is 337°C .

Potassium nitrate contains a large percentage of oxygen, which is readily given up and is well adapted for pyrotechnic compounds. It gives a beautiful violet flame in burning. It is used in flares and in signal rockets.

Most enamels contain some oxidizing agent in the form of potassium or sodium nitrate. Only a small amount of nitrate is necessary; 2%–4% is sufficient to maintain oxidizing conditions in most smelting operations.

In glazes, it is sometimes used as a flux in place of potassium oxide, but, owing to its cost and solubility, very little of it is contained in glaze. Where conditions prevent the use of sufficient potash feldspar, potassium oxide is introduced into the mix, usually in the form of the nitrate in a frit.

Potassium nitrite is a solid of the composition KNO_2 used as a rust inhibitor, for the regeneration of heat-transfer salts, and for the manufacture of dyes.

Potential

Any of various functions from which intensity or velocity at any point in a field may be calculated. The driving influence of an electrochemical reaction. See also *active potential*, *chemical potential*, *corrosion potential*, *critical pitting potential*, *decomposition potential*, *electrochemical potential*, *electrode potential*, *electrokinetic potential*, *equilibrium (reversible) potential*, *free corrosion potential*, *global potential*, *open-circuit potential*, *protective potential*, *redox potential*, and *standard electrode potential*.

Potential Barrier

The atoms in a crystal lattice interact so that each is normally located at the minimum energy level it can reach; it is said to lie in an energy trough or potential trough. If an atom has to be moved, it needs an injection of energy to initiate its movement out of the trough and over the potential barrier (or energy barrier) into the next trough.

Potential Difference

The difference in potential, measured in volts, between two points in the electrical circuit when subject to an electromotive force or carrying a current.

Potential Drop Techniques

A series of techniques for measuring the propagation of a crack by measuring the voltage drop in a constant current imposed across the crack zone. Four contacts are made to the crack zone. One pair

P

placed either side of the crack applies the current; the second pair, similarly placed, measures the potential drop. Depending upon the power supply, the techniques are termed alternating current potential drop and direct current potential drop, usually abbreviated to ACPD and DCPD, respectively.

Potential Energy

The energy contained in some body by virtue of its position relative to another body in circumstances such as a gravitational field.

Potential Trough

See *potential barrier*.

Potential-pH Diagram

See *Pourbaix (potential-pH) diagram*.

Potentiodynamic (Potentiokinetic)

The technique for varying the *potential* of an electrode in a continuous manner at a preset rate.

Potentiometer

An instrument that measures electromotive force by balancing against it an equal and opposite electromotive force across a calibrated resistance carrying a definite current.

Potentiometric Membrane Electrodes

Electrochemical sensing device that can be used to quantify cationic and anionic substances and gaseous species in aqueous solutions. These devices are also used for analytical titrations. See also *titration*.

Potentiostat

(1) An instrument for automatically maintaining an electrode in an electrolyte at a constant potential or controlled potentials with respect to a suitable reference electrode. (2) An instrument for supplying electric current of constant voltage but variable amperage.

Potentiostatic

The technique for maintaining a constant *electrode potential*.

Potentiostatic Etching

The selective corrosion of one or more morphological features of a microstructure that results from holding the metal to be etched in a suitable etching electrolyte at a controlled potential relative to a reference electrode. Adjusting the potential makes possible a defined etching of singular phases.

Pottery

A generic term for all fired ceramic wares that contain clay, except for technical, structural, and refractory products. Specifically, however, pottery describes the low-temperature fired porous ware that

is usually colored. The term is properly applied to the clay products of primitive peoples or to decorative art products made of unrefined clays by using unsophisticated methods. See also *traditional ceramics*.

Poultice Corrosion

A term used in the automotive industry to describe the corrosion of vehicle body parts due to the collection of road salts and debris on ledges and in pockets that are kept moist by weather and washing. Also called deposit corrosion or attack. Differential aeration corrosion is a major contributory factor to the attack. It is a common cause of corrosion on the under surfaces of road vehicles.

Pour Point

The lowest temperature at which a lubricant can be observed to flow under specified conditions.

Pour Welding

A flow welding process. See *burning*.

Pourbaix (Potential-pH) Diagram

A plot of the *redox potential* of a corroding system versus the pH of the system, compiled using thermodynamic data and the *Nernst equation*. The diagram shows regions within which the metal itself or some of its compounds are stable. The diagram identifies corrosion characteristics of a metal in aqueous solutions. The diagram plots electrode potential on the vertical axis and pH on the horizontal. Zones on the diagram indicate circumstances in which the metal acts in a passive, immune, or a corrosive manner.

Pouring

The transfer of molten metal from furnace to ladle, ladle to ladle, or ladle to molds.

Pouring Basin

In metal casting, a basin on top of a mold that receives the molten metal before it enters the sprue or downgate. See *gating system*.

Pour-Point Depressant

An additive that lowers the pour point of a lubricant.

Powder

An aggregate of discrete particles that are usually in the size range of 1–1000 μm .

Powder Cutting/Injection

Oxygen cutting in which a powder, usually iron, is injected into the cutting stream. The iron assists the exothermic reaction as well as providing fluxing and scouring actions. The process can cut high chromium and stainless steel that because of their resistance to oxidation are not readily cut by the normal equipment. See *chemical flux cutting* and *metal powder cutting*.

Powder Feeder

A mechanical device designed to introduce a controlled flow of powder into the plasma-spray torch. See also *plasma spraying*.

Powder Fill

In powder metallurgy, the filling of the die cavity with powder prior to compaction.

Powder Flame Spraying

A thermal spraying process variation in which the material to be sprayed is in powder form. See also *flame spraying*.

Powder Forging

The plastic deformation of a powder-metallurgy *compact* or *preform* into a fully dense finished shape by using compressive force; usually done hot and within closed dies.

Powder Lubricant

In powder metallurgy, an agent or component incorporated into a mixture to facilitate compacting and ejecting of the compact from its mold.

Powder Metallizing

See preferred term *powder flame spraying*.

Powder Metallurgy

(1) The technology and art of producing metal powders and utilizing metal powders for production of massive materials and shaped objects. (2) The manufacture of metal powders and, from them, bulk components by processes such as sintering rather than melting.

Powder Method

Any method of *x-ray diffraction* involving a polycrystalline and preferably randomly oriented powder specimen and a narrow beam of monochromatic radiation. The powder method is best known as a phase characterization tool because it can routinely differentiate between phases having some chemical composition but different crystal structures (polymorphs). See also *polymorphism*.

Powder Molding

General term used to denote several techniques, such as injection molding, for producing objects of varying size and shape by melting plastic powder, usually against the inside of a mold. The molds are either stationary (e.g., in variations of slush molding techniques) or rotating (e.g., in variations of rotational molding).

Powder Plastics Moldings

The term *powder molding* broadly describes a technique of sintering or fusing finely divided thermoplastic materials to conform to the surface of a mold.

Processing

There are a number of processes and techniques loosely termed powder molding. The Engel or Thermofusion process was developed in Europe and sublicensed in the United States in 1960. This patented technique employs inexpensive sheet-metal molds and a hot-air oven heated by either gas or electricity. In essence, the process consists of filling the mold with powdered thermoplastic material, fusing the layer of material next to the mold walls, removing the excess powder, and then smoothing the inside surface with heat.

Another older technique, known as the Heisler process, involves rotating a heated mold. Both of these patented techniques employ an *excess* of powdered material over that required for the object being fabricated; the extra material is removed as one of the processing steps.

More recently, it was discovered that powdered polyethylene behaves enough like a liquid to permit use of rotational casting equipment designed for use with vinyl plastisols. The technique involves multiaxial rotation of a closed mold filled with a *measured* charge of material, all of which is fused during the heating step. This permits fabrication of totally enclosed articles. A hobby horse for children is the most striking example of the versatility of the rotational casting process. There is at present a variety of rotational casting apparatus available. Now engineered specifically for use with powdered thermoplastic materials, it is anticipated that this technique will find widespread acceptance.

The selection of a particular powder-molding technique depends on the application under consideration. The selection depends on factors such as size, wall thickness, geometric configuration, and quantity of parts desired. Rotational casting with a measured charge is obviously indicated where automation for a large volume of production is desired, due to the reduction of material-handling requirements.

Advantages

Because of low tooling costs, all of these various powder-molding processes offer significant economies over conventional fabricating techniques such as injection or blow molding in small or moderately large quantities (up to 250,000 pieces, depending on the application concerned).

Typically, inexpensive sheet-metal or cast aluminum molds may be used, as compared with expensive matched metal molds made of tool steels. The heat source is usually an electric or gas-fired air oven, a small capital cost in comparison to an injection-molding machine or extruder. Moreover, the large size of some objects that are fabricated by powder molding defy production by most other techniques. The size of an object to be fabricated by this particular process is limited only by the size of the oven. Large tanks, refuse containers, and even boats are included in the wide variety of products being fabricated by this method. These parts range in wall thickness from 1.5 to 6.4 mm with a tolerance of $\pm 10\%$ considered reasonable.

Materials Used

Although powder-molding processes are theoretically applicable to any thermoplastic material, current practice has been restricted primarily to polyethylenes of low and intermediate density. As soon as effective stabilizing systems are found for other materials, particularly the broader range of polyolefin materials, it is anticipated that such materials will also find use where their particular properties offered advantages in specific applications. The particles of powder range in size from 30 to 100 mesh (U.S. standard), with the peak of the bell-shaped distribution at approximately 60 mesh. The powder

P

is made by grinding the material in pellet form as an additional manufacturing step.

Production cycles can be cited only generally, as they depend on the application concerned. Cycles range from roughly 3 min for small, thin-walled parts made by rotational casting, to as much as 30 min for very large, heavy-walled parts made by the Engel process.

Powder Production

The process by which a metal powder is produced, such as machining, milling, atomization, condensation, reduction, oxide decomposition, carbonyl decomposition, electrolytic deposition, or precipitation from a solution.

Powder Rolling

See preferred term *roll compacting*.

Powder Technology

A broad term encompassing the production and utilization of both metal and nonmetal powders.

Powder-Feed Rate

In thermal spraying, the quantity of powder introduced into the arc per unit time; expressed in pounds/hour or grams/minute.

Powder-Metallurgy Forging

See *powder forging*.

Powder-Metallurgy (P/M) Parts

Powder-metallurgy parts, commonly referred to as P/M parts, are produced by the P/M process, which involves blending of powders, pressing the mixture in a die, and then sintering or heating the compact in a controlled atmosphere to bond the contacting surfaces of the particles. Where desirable, parts can be sized, coined, or repressed to closer tolerances; they can be impregnated with oil or plastic or infiltrated with a lower-melting metal; and they can be heat-treated, plated, and machined. Production rates range from several hundred to several thousand per hour.

Shapes that can be fabricated in conventional P/M equipment range up to about 16.1 kg. Parts of over 460 kg can be produced with special techniques such as isostatic compacting and extrusion. However, most P/M parts weigh less than 2.3 kg. While most of the early P/M parts were simple shapes, such as bearings and washers, developments over the years in equipment and materials now make economical the production of more intricate and stronger parts. And shapes with flanges, hubs, cores, counterbores, and combinations of these are fairly commonplace.

P/M parts are made from a wide range of materials, including combinations not available in wrought or cast form. And these materials can be processed by P/M techniques to provide tailored densities and parts ranging from porous components to high-density structural and mechanical parts. In addition, almost any conceivable alloy system under equilibrium or nonequilibrium conditions can be achieved, and segregation effects (nonhomogeneities) are avoided or minimized.

Most metal powders are produced by atomization, reduction of oxides, electrolysis, or chemical reduction. Metals available include iron, nickel, copper, and aluminum, as well as refractory

and reactive metals. These metals can be blended together to form different alloy compositions during sintering. Also, prealloys such as low-alloy steels, bronze, brass, nickel-silver, and stainless steel are produced in which each particle is itself an alloy, thus ensuring a homogeneous metallurgical structure in the part. And it is possible to combine metal and nonmetal powders to provide composite materials with the desirable properties of both in the finished part.

The method selected is dictated primarily by composition, intended application, and cost. Typically, metal powders for commercial usage range from 1 to 1200 μm . Depending on the method of production, metal powders exhibited diversity of shapes from spherical to acicular. Particle shape is an important property, because it influences the surface area of the powder, its permeability and flow, and its density after compaction.

Chemical composition and purity also affect the compaction behavior of powders. For most applications, powder purity is higher than 99.5%.

The P/M process is being used to produce many thousands of different parts in most product and equipment manufacturing industries, including automotive, business machines, aircraft, consumer products, electrical and electronic, agricultural equipment, machinery, ordnance, and atomic energy.

The application of P/M parts in these industries falls into two main groups. The first are those applications in which the part is impossible to make by any other method. For example, parts made of refractory metals like tungsten and molybdenum or of materials such as tungsten carbide cannot be made efficiently by any other means. Porous bearings and many types of magnetic cores are exclusively products of the P/M process. The second group of uses consists of mechanical and structural parts that compete with other types of metal forms such as machine parts, castings, and forgings.

Processes

P/M processes include pressing and sintering, powder injection molding, and full-density processing.

Pressing and Sintering

The basic P/M process requires two steps involving powder compaction followed by sintering. First, the rigid steel die (mold) is filled with powder. Pressure is then applied uniaxially at room temperature via steel punches located above and below the powder, after which the compact is ejected from the mold. Commercial compaction pressures are normally in the range from 140 to 900 MPa. The powder compact is porous. Its density depends on compaction pressure and the resistance of the powder particles to deformation; compact densities about 90% of the theoretical level are common.

In the sintering process, the powder compact is heated below its melting point to promote bonding of the solid powder particles. The major purpose of sintering is to develop strength in the compact. Normally an increase in the density of the compact also occurs, but the compact still contains pores. The internal architecture (microstructure) of the material is developed during sintering. As a rule of thumb, the sintering temperature must be higher than one half the melting temperature (Kelvin scale) of the powder.

Normally, parts made by pressing and sintering require no further treatment. However, properties, tolerances, and surface finish can be enhanced by secondary operations. Examples of secondary or finishing operations are repressing, resintering, machining, heat treatment, and various surface treatments such as deburring, plating, and sealing.

Powder Injection Molding

This is a process that builds on established injection-molding technology used to fabricate plastics into complex shapes at low cost. The metal powder is first mixed with a binder consisting of waxes, polymers, oils, lubricants, and surfactants. After granulation, the powder binder mix is injection molded into the shape desired. Then, the binder is removed and the remaining metal powder skeleton sintered. Secondary operations may be performed on the sintered part, similar to those for conventional press-plus-sintered parts. The viscosity of the powder-binder mix should be below 100 Pa·s (1000 poise) with about 40% by volume of binder, and spherical powders less than 20 μm in diameter are preferred. Powder injection molding produces parts that have the shape and precision of injection-molded plastics but that exhibit superior mechanical properties such as strength, toughness, and ductility.

Full-density Powder Processing

Parts fabricated by pressing and sintering are used in many applications. However, their performance is limited because of the presence of porosity. To increase properties and performance and to better compete with products manufactured by other metal working methods (such as casting and forging), several P/M techniques have been developed that result in fully dense materials; that is, all porosity is eliminated. Three examples of full-density processing are hot isostatic pressing, powder forging, and spray forming.

In the hot isostatic pressing process, the metal (or ceramic) powder is sealed in a metallic or glass container, which is then subjected to isostatic pressure at elevated temperature. Temperatures up to 2200°C and pressures up to 200 MPa are possible in modern presses. After complete densification of the powder, the compact is removed and the container stripped from the densified compact. Hot isostatic pressing is applied to the consolidation of nickel and titanium alloys, tool steels, and composites.

Powder forging is an adaptation of conventional forging in which a compact is prepared that is then sintered to retain about 20% by volume of porosity. This preform is transferred to a forging press and formed in a closed die cavity to its final shape with one stroke of the press. All porosity is removed in the forging operation. Powder forging is used primarily to fabricate components from low-alloy steels.

In the spray-forming process, a stream of liquid metal is gas-atomized into a spray of droplets that impinge on a substrate. The spraying conditions are such that the droplets arrive at the substrate in the semisolid state. By control of the geometry and motion of the substrate, it is possible to fabricate sheet or plate, tubes, and circular billets. It is a rapid process with a deposition rate up to about 2 kg/s. Applications include aluminum, copper, iron, and nickel alloys.

Characteristics and Applications

P/M competes with several more conventional metalworking methods in the fabrication of parts, including casting, machining, and stamping. Characteristic advantages of P/M are close tolerances, low cost, net shaping, high production rates, and controlled properties. Other attractive features include compositional flexibility, low tooling costs, available shape complexity, and a relatively small number of steps in most P/M production operations. Control of the level of porosity is the intrinsic feature of P/M that enables the parts produced to predict and specify physical mechanical properties during fabrication. Broad areas of usage for P/M parts include structural (load bearing) components and controlled-porosity, electrical, magnetic, thermal, friction, corrosion-resistant, and wear-resistant applications. Industries that make extensive use of P/M parts are

aerospace, agricultural, automotive, biomedical, chemical processing, and electrical. In addition, the fabricators of domestic appliances and office equipment are dependent on the availability of a wide range of sizes and geometries of P/M parts exhibiting unique combinations of physical and mechanical properties.

Ferrous parts fabricated by pressing and sintering make up the largest segment of the P/M industry, and a majority of the applications are for the automotive market. Representative P/M parts include gears, bearings, rod guides, pistons, fuel filters, and valve plates. In the nonautomotive sector, examples of parts include gears, levers, and cams, lawn tractors and garden appliances, and gears, bearings, and sprockets in office equipment.

Full-density processing has been used in the powder forging of steel automobile connecting rods. The iron-copper-carbon rod is forged to a minimum density of 7.84 g/cm³.

Important characteristics of powder forging include straightness, illumination of surface defects inherent in conventional forging, uniform microstructure, dimensional control, and superior machinability. Secondary operations include deflashing, shot peening, and machining.

An example of a part manufactured by powder injection molding is a miniature read/write latch arm made from stainless steel powder and used in a small-capacity hard disk drive. The geometric form of the entire outside profile of the part is very critical relative to the pivot hole. Coining is the only secondary operation.

Safety and Health Considerations

Because metal powders possess a high surface area per unit mass, they can be thermally unstable in the presence of oxygen. Very fine metal powders can burn in air (pyrophoricity) and are potentially explosive. Therefore, the clean handling of powder is essential; methods include venting, controlled oxidation to passivate particle surfaces, surface coating, and minimization of sparks or heat sources. Some respirable fine powders pose a health concern and can cause disease or lung dysfunction; the smaller the particle size, the greater the potential health hazard. Control is exercised by the use of protective equipment and safe handling systems such as glove boxes. There is no recognized hazard associated with the normal handling of the common grades of metal and alloy powders such as copper and iron.

Power Factor (Electricity)

(1) The ratio of the power to the effective values of the electromotive force multiplied by the effective value of current, in volts and amperes, respectively. The cosine of the angle between voltage applied and the resulting current. (2) The multiplication factor applicable to voltage (volts) $\times$ current (amperes) to give power (watts) in an alternating current circuit. In an alternating current circuit with any significant amount of inductance or capacitance, the wave forms for voltage and current will be out of phase with each other. The vector of the degree of out of phase is represented by f and the power factor is then $\cos f$. Hence, power = volts $\times$ amps $\times \cos f$.

Power Reel

A reel that is driven by an electric motor or some other source of power, used to wind or coil strip or wire as it is drawn through a continuous normalizing furnace, through a die, or through cool rolls.

Power-Driven Hammer

A forging hammer with a steam or air cylinder for raising the ram and augmenting its downward blow. Also known as power drop hammer. See also *drop hammer* and *gravity hammer*.

P

PP

See *polypropylenes*.

PPE

Polyphenylene ether. See also *polyphenylene oxides*.

PPO

See *polyphenylene oxides*.

PPS

See *polyphenylene sulfides*.

Praseodymium

A metallic element, one of the rare earths group.

Prealloyed Powder

A metallic powder composed of two or more elements that are alloyed in the powder manufacturing process and in which the particles are of the same nominal composition throughout.

Prearc (or Prespark) Period

In emission spectroscopy, the time interval after the initiation of an arc (or spark) discharge during which the emitted radiation is not recorded for analytical purposes.

Prebond Treatment

Synonym for surface preparation prior to *adhesive bonding*.

Precharge

In metal forming, the pressure introduced into the cavity prior to forming of the part.

Precious Metals

These are the metals gold, silver, and platinum, which are used for coinage, jewelry, and ornaments and also for industrial applications. Expense or rarity alone is not the determining factor; rather, a value is set by law, with the coinage having an intrinsic metal value as distinct from a copper coin, which is merely a token with little metal value. The term noble metal is not synonymous, although a metal may be both precious and noble, as platinum. Although platinum was once used in Russia for coinage, only gold and silver fulfill the three requisites for coinage metals. Platinum does not have the necessary wide distribution of source. The noble metals are gold, platinum, iridium, rhodium, osmium, and ruthenium. Unalloyed, they are highly resistant to acids and corrosion. Radium and certain other metals are more expensive than platinum but are not classed as precious metals. Because of the expense of the noble metals, they may be alloyed with gold for use in chemical crucibles.

The eight precious metals, listed in order of their atomic number found in periods 5 and 6 (groups VIII and Ib) of the periodic table, are ruthenium, rhodium, palladium, silver, osmium, iridium,

platinum, and gold. Precious metals, also referred to as noble metals, are of inestimable value to modern civilization. Their functions in coins, jewelry, and bullion, and as catalysts in devices to control auto exhaust emissions, are widely understood. But in certain applications, their functions are not as spectacular and, although vital to the application, are largely unknown except to the users. For example, precious metals are used in dental restorations and dental fillings; thin precious metal films are used to form electronic circuits, and certain organometallic compounds containing platinum are significant drugs for cancer chemotherapy.

Silver is a bright, white metal that, next to gold, is the most easily fabricated metal in the periodic table. It is very soft and ductile in the annealed condition. Silver does not oxidize at room temperature, but it is attacked by sulfur. Nitric, hydrochloric, and sulfuric acids attack silver, but the metal is resistant to many organic acids and to sodium and potassium hydroxide. The primary application for silver (about 50% of the silver demand) is its use for photographic emulsions. The use of silver in photography is based on the ability of the exposed silver halide salts to undergo a secondary image amplification process called development. The second largest use is in the electrical and electronic industries for electrical contacts, conductors, and primary batteries. Other applications include brazing filler metals, dental alloys, electroplated ware, sterling wear (see *sterling silver*), and jewelry and coins.

Gold is a bright, yellow, soft, and very ductile metal. Its special properties include corrosion resistance, good reflectance, resistance to sulfidation and oxidation, and higher electrical and thermal conductivity. Because gold is easy to fashion, has a bright pleasing color, is nonallergenic, and remains tarnish-free, definitely, it is used extensively in jewelry (about 55% of the gold market). For much the same reasons, it is used in dental alloys and appliances. Gold is also used to a considerable extent in electronic devices, particularly in printed circuit boards, connectors, keyboard contactors, and miniaturized circuitry. Other applications include gold films used as a reflector of infrared radiation in thermal barrier windows for large buildings and space vehicles, fired-on gold organometallic compounds used for decorating glass in china, sliding electrical contacts, and brazing filler metals.

The six remaining precious metals are referred to as the platinum group metals because they are closely related and commonly occur together in nature. Ruthenium, rhodium, and palladium each have a density of approximately 12 g/cm³; osmium, iridium, and platinum each have a density of about 22 g/cm³. The most distinctive trait of the platinum group metals is their exceptional resistance to corrosion. Of the six metals, platinum has the most outstanding properties and is mostly used, the primary application being its use as an automobile exhaust emission catalyst. Second in industrial importance is palladium, which is used primarily in electrical applications. Rhodium and ruthenium are used as alloying elements in platinum and palladium, while osmium and iridium are used for wear-resistant and heat-resistant applications, respectively.

Precipitate

Particles that emerge from a supersaturated solution. See *phase* and *solution*.

Precipitation

In metals, the separation of a new phase from solid or liquid solution, usually with changing conditions of temperature, pressure, or both.

Precipitation (Deposit) Etching

Development of microstructure in a metallographic specimen through formation of reaction products at the surface of the micro-section. See also *staining*.

Precipitation Hardening

Hardening of an alloy as a result of a phase precipitating, or partially precipitating, from a supersaturated solid solution. Some alloys have compositions selected so that all or most of the minor constituents are in solid solution at high temperature but form a second phase at ambient temperature under equilibrium conditions. These characteristics can be manipulated to induce hardening of the alloy by a heat treatment cycle. The effects can be illustrated by reference to aluminum alloys containing, for example, small amounts of copper, silicon, and magnesium. The initial stage of the cycle is solution treatment in which the metal is heated to about 480°C for about 30 min and then cooled rapidly. This retains the alloying elements in supersaturated solid solution. In this condition, the material is relatively soft and ductile allowing it to be formed to final shape. The material subsequently undergoes a precipitation process in which it hardens progressively, with an associated loss of ductility, as the alloying elements commence to come out of solution. This can occur, in certain alloys, over a few days at normal temperature, a process referred to as natural aging. Alternatively, it may be induced by heating for a few hours at about 170°C referred to as artificial aging, precipitation treatment, warm hardening, warm aging, or similar terms. Maximum hardening is achieved when the growing precipitates remain partially coherent with the parent phase lattice. This approximates to the stage just before the emerging precipitates become visible under an optical microscope. See also *Guinier–Preston zones*. If the temperature or time is excessive, the precipitation process continues to completion, the material progressively softens, and it is termed overage. See *age hardening and aging*.

Precipitation Heat Treatment

Artificial aging of metals in which a constituent precipitates from a supersaturated solid solution.

Precision

The reproducibility of measurements within a set, that is, the scatter or dispersion of a set of data points about its central axis. Generally expressed as standard deviation or relative standard deviation.

Precision Casting

(1) A metal casting of reproducible, accurate dimensions, regardless of how it is made. Often used interchangeably with *investment casting*. (2) The lost wax process.

Precision Forging

A forging produced to closer tolerances than normally considered standard by the industry. With precision forging, a net shape, or at least a near-net shape, can be produced in the as-forged condition. See also *net shape*.

Precision Grinding

Machine grinding to specified dimensions and low *tolerances*.

Precoat

(1) In investment casting, a special refractory slurry applied to a wax or plastic expendable pattern to form a thin coating that serves as a desirable base for application of the main slurry. See *investment casting*. (2) To make the thin coating. (3) The same coating itself.

Precoated Metal Products

Mill products that have a metallic, organic, or conversion coating applied to their surfaces before they are fabricated into parts.

Precoating (Joining)

Coating the base metal in the joint by dipping, electroplating, or other applicable means prior to brazing or soldering.

Preconditioning

Any preliminary exposure of a plastic to specified atmospheric conditions for the purpose of favorably approaching equilibrium with a prescribed atmosphere.

Precracked Specimen

A mechanical test specimen that is notched and subjected to alternating stresses until a crack has developed at the root of the notch.

Precure

The full or partial setting of a synthetic resin or adhesive in a joint before the clamping operation is complete or before pressure is applied. See also *cure*.

Precursor

With respect to carbon or graphite fiber, the rayon, polyacrylonitrile, or pitch fibers from which carbon and graphite fibers are derived. See also *carbon fiber*, *pitch*, and *polyacrylonitrile (PAN)*.

Preferred Orientation

A condition of a polycrystalline aggregate in which the crystal orientations are not random, but rather exhibit a tendency for alignment with a specific direction in the bulk material, commonly related to the direction of working. See also *texture* and *orientation*.

Prefinished Metals

Prefinished metals are sheet metals that are precoated or treated at the mill so as to eliminate or minimize final finishing by the user. The metals are made in a ready-to-use form with a decorative and/or functional finish already applied. Prefinished metals provide many advantages including: (1) better product appearance, (2) lower product cost, (3) greater product uniformity, and (4) improve product function. (See Table P.1, which reflects types of prefinished metals.) It is possible to obtain base metal preplated with almost any decorative or functional metal, from bright, shiny chromium to dull, rich-looking brass. Similarly, it is possible to obtain sheet with pre-painted surfaces in almost every color and in a wide variety of special-purpose plastic resins. Also, where extra durability or a special decorative effect is needed, some of these resins, notably polyvinyl

TABLE P.1

Types of Prefinished Metals

Material	Surface Composition, Appearance	Base Metals
Preplated metals	Nickel, chromium: Excellent appearance; available in dull, satin, and bright (sometimes provided with a clear lacquer coating for added protection) finishes, many of which can be embossed with wide range of patterns). Brass, copper: Excellent appearance; available in dull, satin, and highly polished finishes, many of which can be embossed with wide range of patterns. Zinc: Natural grayish finish that can be used to improve product appearance by providing with semilustrous finish and coating with clear lacquer.	Steel, zinc, brass, copper, aluminum. Steel, zinc. Steel.
Prepainted metals	Almost every organic coating is available or can be ordered in prepainted form. Selection of coating resin depends on end-use requirements. Five most popular prepainted metals now in use are alkyds, acrylics, vinyls, epoxies, and epoxy-phenolics. Many coatings can be pigmented to provide metallike appearance.	Most common ferrous and nonferrous metals. For added protection, the reverse side of ferrous metals is usually given a rust-preventive treatment or provided with an organic or metallic coating. Selection of base metal depends on cost, appearance, and product life requirements. Most popular base metals are cold-rolled steel, tinplate, tin mill backplate, hot-dipped and electrogalvanized steel, and standard aluminum alloys.
Plastic-metal laminates	Vinyl (PVC)-metal: PVC sheet laminated to base metal with thermosetting adhesives under heat and pressure (25–60 psi). Vinyl (PVF)-metal: PVF film laminated to base metal with thermosetting adhesive under heat and pressure. Polyester-metal: Polyester film laminated to base metal.	Can be applied to most metals; popular are steel, provides strength at low cost and the reverse side can be painted or provided with corrosion-resistant coating; aluminum, lightweight and/or corrosion resistant; magnesium, lightweight. Cold-rolled steel, provides strength at low cost; galvanized, aluminized, and tin-plated steel, corrosion resistant; aluminum, lightweight and corrosion resistant. Usually steel.
Textured and embossed metals	Surfaces available in hundreds of different textures and patterns. Available with texture on one surface only or with pattern that extends completely through cross section of metal. Also available in perforated form. Surfaces can be provided with dull satin or highly polished finish or combinations thereof (e.g., dull background with polished highlights). Can also be painted, porcelain enameled, or oxidized; these finishes can be buffed off high spots to provide two-tone effect.	All common sheet metals, including carbon steel, strength at low cost; stainless steel, corrosion resistance plus strength; aluminum, lightweight plus corrosion resistant; copper, pleasing appearance plus strength and corrosion resistance.
Hot-dipped other plated metals	Galvanized (zinc coated): Zinc surface with intermediate zinc-iron alloy layer. Aluminized: Aluminum surface; intermediate aluminum-iron layer forms above 900°F. Tin coated: Hot dipped or electroplated tin. Terne or lead coated: Lead-tin alloys, pure lead.	Steel, ingot iron. Steel. Mild carbon steel. Steel.
Specially finished aluminum	Color anodized: Anodized aluminum available in clear, yellow gold (70:30 brass), red gold, rich low brass (85:15 brass), copper, blue, green, red, and black. Colors are obtainable over standard mill, satin, and bright finishes, as well as over embossed and perforated textures. Spangled: Uncoated surface containing large grains that stand out in relief and facets that break up and reflect light. Available in wide variety of colors and mill finishes.	All commercial aluminum alloys and tempers. Wrought aluminum alloys.

chloride (PVC), are available in sheet or film, laminated to several different metals.

Furthermore, almost every metal is available in a limitless number of textured, patterned, and embossed finishes right from the mill. These textured metals can be used as is, but even they can be supplied preplated, prepainted, or even with a colored preanodized finish, as in the case of aluminum.

Many sheet metals are also available with galvanized, aluminized, tin, and terne coatings. These materials, especially galvanized, were among the first prefinished metals to be developed and remain today as basic prefinished metals.

Functional Advantages

Many prefinished metals are used for functional applications. Practically, all zinc-plated sheet, for example, is used in functional applications where good corrosion resistance, rather than a bright, decorative finish is wanted (e.g., condenser cans and hidden parts and door locks). The zinc coating also provides a good paint base, provided the surface is first given a chemical conversion treatment.

Copper-plated steel is another good example of a functional finish. It provides a good lubricating surface for deep-drawing operations and also makes a good base for further electroplating. The material is also used for its electrical conductivity, for its usefulness in low-temperature tinning and high-temperature brazing operations, and as a stop-off coating in carburizing operations.

Prepainted metals are also popular for functional applications; this is borne out by the wide number of functional resins that are now available. In addition to providing decorative appearance, these coatings prevent the base metal from corroding and can provide good resistance to chemicals and foods (epoxies), toughness and resistance to forming damage (vinyls), and good resistance to outdoor exposure (acrylics).

Types and Applications

Prepainted metals are produced using various organic coatings on many common ferrous and nonferrous metals. Extra durability or special decorative effects are provided by plastic-metal laminates. PVC, polyvinyl fluoride, and polyester are the plastics commonly used.

Black-coated steel is used to give a high thermal emittance in electronic equipment. The base metal is aluminum-deoxidized steel containing 0.13% carbon, 0.45% manganese, 0.04% max phosphorus, and 0.05% max sulfur. The steel is coated with a 5% by weight layer of nickel oxide, which is reduced in a hydrogen furnace to form a spongy layer of nickel. This sponge is impregnated with a carbon slurry to form a black carbonized surface.

Preplated metals consist of a thin electrodeposited plate of one metal or alloy on a base, or substrate, usually sheet, of another metal. Steel is the most common base metal, and it is commonly plated with brass, chromium, copper, nickel, nickel-zinc, or zinc. Other common preplated metals are chromium-plated brass, copper, nickel, or zinc, and nickel-plated brass, copper, or zinc. The surface of the plate may be mirror bright, satin, bright satin, embossed, antique, or black or have some other finish. The plate, usually 0.025–0.127 mm thick, is sufficiently ductile to withstand shearing, bending, drawing, and stamping operations. Joining methods include lock seaming, stud welding, adhesive bonding, and spot welding. One of the earliest groups of preplated metals included Brassoid, Nickeloid, and Chromaloid, which were brass-, nickel-, and chromium-plated zinc sheet.

Prefinished metals are now available with almost any metal plated or bonded to almost any other metal, or single metals may

be prefinished in colors and patterns. They come in bright or matte finishes and usually have a thin paper coating on the polished side, which is usually stripped off before or after forming. The metals are sold under a variety of trade names and are used for decorative articles, appliances, advertising displays, panels, and mechanical parts.

Prefit

A process for checking the fit of mating detail parts in an assembly prior to *adhesive bonding* to ensure proper bond lines. Mechanically fastened structures are sometimes prefitted to establish shimming requirements.

Preform (Ceramics)

A porous ceramic mass in the shape of the desired final part that is infiltrated with metal to form ceramic-metal composite. See also *Lanxide process*.

Preform (Composites and Plastics)

A preshaped fibrous reinforcement formed by the distribution of chopped fibers or cloth by air, water floatation, or vacuum over the surface of a perforated screen to the approximate contour and thickness desired in the finished part. Also, a preshaped fibrous reinforcement of mat or cloth formed to the desired shape on a mandrel or mock-up before being placed in a mold press. (2) A compressed tablet or biscuit of plastic composition used for efficiency in handling and accuracy in weighing materials. (3) To make plastic molding powder into pellets or tablets.

Preform (Joining)

Brazing or soldering filler metal fabricated in a shape or form for a specific application.

Preform Binder

A resin applied to the chopped strands of a *preform*, usually during its formation, and cured so that the preform will retain its shape and can be handled.

Preformed Ceramic Core

In foundry practice, a preformed refractory aggregate inserted in a wax or plastic pattern to shape the interior of that part of a casting that cannot be shaped by the pattern. The wax is sometimes injected around the preformed core. See also *investment casting*.

Preforming

(1) The initial pressing of a metal powder to form a compact that is to be subjected to a subsequent pressing operation other than coining or sizing. (2) Preliminary forming operations, especially for impression die forging.

Pregel

An unintentional, extra layer of cured resin on part of the surface of a reinforced plastic. Not related to gel coat.

Precipitation Hardening

Precipitation hardening is the method now employed to impart high strength at high temperatures to most of the superalloys used for critical components of aircraft gas turbines. This includes alloys ranging from 25% nickel A-286 wheel alloys to such recent and complex high-temperature nickel-base wrought and cast turbine blade alloys as “Udimet” 700, “Nimonic” alloy 115, and IN-100.

The presence of aluminum and titanium, usually jointly, in a nickel–chromium base, with or without iron, imparts unique age-hardening characteristics through the precipitation of gamma-prime phase $\{\text{Ni}_3(\text{Al,Ti})\}$.

The outstanding difference between the previously used age-hardening systems, typified by duralumin or beryllium copper, and those utilizing gamma-prime hardening lies in the fact that an alloy of the latter type can be heated in service appreciably above the optimum aging temperature without permanent loss of strength. In the conventional critical dispersion type age-hardening alloys, strength can only be restored by a complete cycle of heat treatment involving a high-temperature solution treatment and reaging.

The difference between the two types of age-hardening systems is that the aluminum–titanium hardened alloy retains most of its initial hardness (and high-temperature properties) when the overheat is removed. However, an alloy typical of the other type of system (such as beryllium copper or beryllium nickel) overages and does not regain its hardness when the overheat is removed. It is this “reversible” aging behavior, along with high resistance to overaging (agglomeration of gamma-prime hardening phase), that has led to the widespread use of aluminum–titanium age-hardened nickel-base alloys for first-stage turbine blades in commercial and advanced design jet engines. The somewhat less complex iron–nickel–chromium alloys, such as A-286 and “Incoloy” alloy 901, used for turbine disks, are similarly age-hardened, with Ni_3Ti comprising most of the age-hardening component in these two alloys. Sufficient aluminum is also present in the gamma-prime precipitate to improve structural stability.

Carbide Hardening

Carbides provide a major source of dispersed-phase strengthening and cobalt-base alloys. These alloys do not respond to age hardening with aluminum and titanium since the gamma-prime phase does not form unless substantial amounts of nickel are present. Although gamma prime $\{\text{Ni}_3(\text{Al,Ti})\}$ is the principal strengthener in the age-hardenable nickel-base alloys, important auxiliary strengthening can be obtained by precipitation of quite complex carbides. The nature of the carbides formed and their mode of distribution can usually be controlled by alloy formation in heat treatment.

Deoxidizers and Malleabilizers

In addition to the major alloying elements, small but effective amounts of malleabilizers such as boron and zirconium must be present to neutralize the effects of impurities that adversely affect hot ductility. As little as 0.005% boron is highly effective in nickel-base alloys, and zirconium, in a concentration about 10 times that of boron, is also useful. In air melting of nickel-base alloys, magnesium is also added to “fix” any sulfur picked up during melting.

The high-temperature properties of the age-hardenable alloys are governed to a large degree by the hardener (aluminum plus titanium) content. However, as the hardener increases, the temperature of incipient fusion decreases and a lower-temperature limit of forgeability rises, because of increased high-temperature strength, until forging is no longer practical by conventional procedures. The use

of cast turbine blade alloys to meet very high-temperature requirements is a natural consequence.

While other co-present elements and the amount of hot and cold workability required are also factors, it may be considered that alloys with up to 4% total hardener (aluminum plus titanium) are generally available in all common mill forms and/or fabricable by conventional methods. As the hardener increases to about 8% or 9%, wrought alloys are still available, but in progressively fewer forms, ultimately being limited to small forgings such as turbine blades, at increasingly greater cost. The commercial cast turbine blade alloys contain from about 7% to 11% total hardener and are often chosen over forgings for reason of cost or necessity or both.

Phases

Superalloys consist of a face-centered cubic (fcc) austenitic gamma-phase matrix plus a variety of secondary phases. The principal secondary phases are carbides (MC , M_{23}C_6 , M_6C , and then M_7C_3) in all superalloy types and gamma-prime (γ) fcc ordered $\text{Ni}_3(\text{Al,Ti})$ intermetallic compound in Ni- and Fe–Ni-based alloys. In alloys containing niobium and tantalum, the primary strengthening phase is gamma double prime (γ'), a body-centered tetragonal phase. Superalloys derive their strength from solid-solution hardeners and precipitating phases. Carbides may provide limited strengthening directly (e.g., through dispersion hardening) or, more commonly, indirectly (e.g., by stabilizing grain boundaries against excessive shear). In addition to those elements that produce solid-solution hardening and promote carbide and γ formation, other elements (e.g., boron, zirconium, hafnium, and cerium) are added to enhance mechanical and/or chemical properties.

The three types of superalloys (Fe–Ni-, Ni-, and Co-base) are further subdivided into wrought, cast, and powder metallurgy alloys. Cast alloys can be further broken down into polycrystalline, directionally solidified, and single-crystal superalloys. The most important class of Fe–Ni-base superalloys includes those alloys that are strengthening by intermetallic-compound precipitation in an fcc matrix. The most common precipitate is γ , typified by alloys A-286 and Incoloy 901, but some alloys precipitate γ' , typified by Inconel 718. Another class of cast Fe–Ni-base superalloys is hardened by carbides, nitrides, and carbonitrides; some tungsten and molybdenum may be added to produce solid-solution hardening. Other Fe–Ni-base alloys are modified in stainless steels primarily strengthened by solid-solution hardening.

The most important class of Ni-base superalloys is strengthened by intermetallic-compound precipitation in an fcc matrix. The strengthening precipitate is γ , typified by Waspaloy and Udimet 700. Another class is represented by Hastelloy X, which is essentially solid-solution strengthened, but which also derives some strengthening from carbide precipitation produced through a working-plus-aging schedule. A third class includes oxide dispersion strengthened (ODS) alloys, which are strengthened by dispersions of inert particles such as yttria.

Cobalt-base superalloys are strengthened by solid-solution alloying and carbide precipitation. Unlike the Fe–Ni- and Ni-base alloys, no intermetallic phase has been found that will strengthen Co-base alloys to the same degree that γ or γ' strengthens the other superalloys.

Compositions and Properties

Although factors such as tensile properties, corrosion resistance, fatigue strength, expansion characteristics, etc., are important, the creep-rupture characteristics are usually the prime requisite in the selection of a superalloy.

Vacuum Melting

Vacuum induction-melted superalloys are generally more ductile than air-melted material, permitting the use of higher aluminum plus titanium levels while still retaining adequate ductility. Vacuum induction melting accomplishes refining and also permits closer control of composition than does air melting. The vacuum arc (consumable electrode) method is widely used for superalloys, especially those employed for turbine disks. Often the electrode for the vacuum arc-melting charge is obtained from a vacuum induction melt, the end product thus combining the benefits of refining occurring in vacuum induction melting with the controlled solidification and sound the ingot structure associated with the vacuum arc process. Some refining is also accomplished in the vacuum arc process, but to a lesser degree than in vacuum induction melting.

Iron-Base Superalloys

The iron-base superalloys include solid-solution alloys and precipitation hardening (PH), or precipitation-strengthened, alloys. Solid-solution types are alloyed primarily with nickel (20%–36%) and chromium (16%–21%), although other elements are also present in lesser amounts. Superalloy 16-25-6, for example, the alloy designation indicating its chromium, nickel, and molybdenum contents, respectively, also contain small amounts of manganese (1.35%), silicon (0.7%), nitrogen (0.15%), and carbon (0.06%). Superalloy 20Cb-3 contains 34% nickel, 20% chromium, 3.5% copper, 2.5% molybdenum, as much as 1% columbium, and 0.07% carbon. Incoloy 800, 801, and 802 contain slightly less nickel and slightly more chromium with small amounts of titanium, aluminum, and carbon. N-155 or Multimet, an early sheet alloy, contains about equal amounts of chromium, nickel, and cobalt (20% each), +3% molybdenum, 2.5% tungsten, 1% columbium, and small amounts of carbon, nitrogen, lanthanum, and zirconium. At 732°C, this alloy has a 1000 h stress-rupture strength of about 165 MPa.

PH iron-base super alloys provide greater strengthening by precipitation of a nickel–aluminum–titanium phase. One such alloy, which may be the most well-known of all iron-base superalloys, is A-286. It contains 26% nickel, 15% chromium, 2% titanium, 1.25% molybdenum, 0.3% vanadium, 0.2% aluminum, 0.04% carbon, and 0.005% boron. At room temperature, it has a tensile yield strength of about 690 MPa and a tensile modulus of 145×10^3 MPa. At 649°C, tensile yield strength declines only slightly, to 607 MPa, and its modulus is about the same or slightly greater. It has a 1000 h stress-rupture strength of about 145 MPa at 732°C. Other PH iron-base superalloys are Discoloy, Haynes 556 (whose chromium, nickel, cobalt, molybdenum, and tungsten content is similar to that N-155); Incoloy 903 and Pyromet CTX-1, which are virtually chromium-free but high in nickel (37%–38%) and cobalt (15%–16%); and V-57 and W-545, which contain about 14% chromium, 26%–27% nickel, about 3% titanium, 1%–1.5% molybdenum, plus aluminum, carbon, and boron. V-57 has a 1000 h stress-rupture strength of about 172 MPa at 732°C and greater tensile strength but similar ductility, than A-286 at room and elevated temperatures.

Nickel-Base Superalloys

Nickel-base superalloys are solid-solution, precipitation, or oxide-dispersion strengthened. All contain substantial amounts of chromium, 9%–25%, which, combined with the nickel, accounts for their excellent high-temperature oxidation resistance. Other common alloying elements include molybdenum, tungsten, cobalt, iron, columbium, aluminum, and titanium. Typical solid-solution alloys

include Hastelloy X (22%–23% chromium, 17%–20% iron, 8%–10% molybdenum, 0.5%–2.5% cobalt, 2% aluminum, 0.2%–1% tungsten, and 0.15% carbon); Inconel 600 (15.5% chromium, 8% iron, 0.25% copper maximum, 0.08% carbon); and Inconel 601, 604, 617, and 625, the latter containing 21.5% chromium, 9% molybdenum, 3.6% columbium, 2.5% iron, 0.2% titanium, 0.2% aluminum, and 0.05% carbon. At 732°C, wrought Hastelloy X (it is also available for castings) has a 1000 h stress-rupture strength of about 124 MPa, and has high oxidation resistance at temperatures to 1204°C.
